The essential factor in fixation of a Colles' fracture is the control of the *posterior* aspect of the whole forearm wrist, and dorsum of the hand

as far as the metacarpophalangeal joints. No standard splints, ancient or modern, can compare with a plaster-of Paris strip applied directly to the skin of the extensor surface. The plaster "gutter" should embrace not more than two-thirds of the circumference of the limb should be closely moulded over the lower end of the radius, and trimmed to allow free movements of the thumb. During the application of the plaster, and until its setting is complete, strong traction must be maintained on the hand by an assistant. At the same time the fracture is moulded between the thenar eminences of the surgeon. This enables one to ensure both the final correction of the backward tilt and the approximation of the multiple fragments where comminution is present.

Period of immobilization. Conflicting views are held regarding the length of time a Colles' fracture should be completely immobilized. In this connection I suggest that two guiding principles should determine our practice: (1) No Colles' fracture in which there has been an appreciable displacement is firmly consolidated before the end of the fifth or sixth week. (2) Every injured joint needs an adequate period of complete rest before being subjected to strain. In the treatment of elbow joint fractures in children the necessity for absolute rest is universally admitted, but in relation to the treatment of Colles' fracture there is no such unanimity. I am convinced beyond all doubt that the practice of immobilizing a Colles' fracture without interruption for a minimum period of 5 weeks is based on correct physiological and mechanical principles. During this stage the limb should not, of course, be entirely idle. Following the teaching of Boehler, the patient is instructed to carry out daily a regular scheme of activity in all joints of the upper limb except those which for the time being are securely immobilized, viz., the wrist and inferior radio-ulnar joints. For the greater part of this time no sling should be worn.

Experience in the treatment of Colles' fracture on a large scale has impressed me with the potential risks of recurrence of deformity, in spite of careful fixation. This tendency to secondary deformity is seen after the second week. It has been said with some truth that secondary deformation often represents a failure to obtain a complete reduction of the fracture at the time of the original setting. I am satisfied however, that in certain circumstances after a perfect primary reduction a backward tilt of the lower fragment may reappear at the critical period between the second and third weeks. For this reason it is wise always to check the position of the fracture by

radiograms after the second week. If the slightest change is discovered in the position of the lower fragment the plaster should be removed, the fracture remoulded and a new plaster applied. This is usually possible without anesthesia. Since the adoption of this routine in my own fracture clinic secondary deformity has become practically unknown.

Mobilization. On removal of the plaster gutter where the fracture has been immobilized without interruption for not less than 5 weeks, the excellent nutritional condition of the limb is always striking. There is no edema and all digital joints are supple and painless. The wrist and inferior radio-ulnar joints also allow a short range of movement without discomfort. Although in the majority of cases the patient may now be entrusted to work out his own salvation by active movements, he should not be left entirely to his own devices. The pace of mobilization should be determined by the anatomy of the fracture. Where there has been marked comminution, or involvement of the inferior radio-ulnar articulation, or where the wrist is the seat of a pre-existing arthritis, the joints should be allowed to take strain very gradually. Overzealous active mobilization in such circumstances may spoil the ultimate functional result. Forced mobilization in any fracture will be disastrous.

The services of a masseuse, except in a supervisory capacity, are redundant in a considerable proportion of Colles' fractures. But in many of the older patients, particularly those with ar-

thritic wrists, a judicious scheme of physical treatment is helpful at this stage.

RESULTS

Some years ago, when the subject of Colles' fracture had excited renewed interest among British surgeons, I was able to investigate the late results in 111 of the patients treated during the 1925-28 period in my hospital fracture service. The findings are shown in the table.

Result	Fractures without displacement	Fractures with displacement
Excellent (including perfect)	18	74
Good—that is, able to do original work, but some slight objective or subjective defect	6	10
Poor		3

In a more recent series of 200 consecutive cases treated under similar circumstances, the average period of total disability has been reduced to 8 weeks. These figures are in no way exceptional. I quote them merely to illustrate the quality of result which is now demanded from an organized hospital fracture service where there is unity of control.

It is the duty of those of us who are responsible for teaching the treatment of fractures in the medical schools to ensure that our students, both undergraduate and postgraduate, will be more competent in the future to handle a common injury like Colles' fracture with some degree of precision. We can do this only if our practice is founded on sound physiological and mechanical principles.

RECURRENT DISLOCATION OF THE SHOULDER¹

TOUFICK NICOLA, M.D., F.A.C.S NEW YORK, NEW YORK

THIS article is written because of the many inquiries regarding the operation for recurrent dislocation of the shoulder which the author first published in 1929.¹

The operation was worked out on the cadaver in 1926 in the dissecting room of the New York Post-Graduate Hospital. On the cadaver the head of the humerus could not be completely dislocated, even though all the muscles and capsule were severed.

The idea of the operation was obtained from an articulated skeleton in which the humerus was held in place by a metal pin, passed through the head of the humerus and attached to the upper angle of the glenoid fossa.

The operation is justified on the grounds of comparative anatomy. Dr Stockard called attention to the fact that in the dog the head of the biceps runs through the head of the humerus, and he was surprised that surgeons had not discovered this long before.

The following is the technique of the operation which I feel will give the best results:
1 The incision begins just outside the coracoid and passes downward for 3 inches in the line of the fibers of the deltoid.

2 The deltoid fibers are divided by blunt dissection. At this point the circumflex nerve and artery may come into view crossing the wound. Care should be taken to avoid injuring them. If the nerve is cut we get paralysis of the anterior part of the deltoid. Although this does not affect the outcome of the operation, it may be objectionable in women.

3 The tendon of the long head of the biceps is located by feeling for the bicipital groove. The transverse humeral ligament, which holds the tendon in the groove, is nicked with a knife and then with scissors. The tendon is exposed up to the shoulder joint. In this step of the operation cutting of the tendon may be avoided by not closing the blades of the scissors while splitting the capsule.

4. The upper edge of the tendon of the pectoralis major muscle is located in the lower angle of the wound. The tendon of the long head of the biceps is divided $\frac{1}{2}$ inch above this, after stay sutures of black silk have been placed in the proximal and distal parts. If this is not done, the

distal part will disappear under the tendon of the pectoralis major muscle, thereby prolonging the operation. The elbow is flexed about 45 degrees during this step and throughout the rest of the operation. The synovial membrane covering the tendon should be removed without fail, so that the tendon becomes fixed in the tunnel in the head of the humerus through which it is passed later.

5 By means of a $\frac{3}{4}$ inch long shank gouge a hole is made through the head of the humerus. This begins in the bicipital groove about 1 inch distal to the lesser tuberosity. The gouge should be so directed that it comes out on the articular head of the humerus in the line of the direction of the tendon, from $\frac{1}{2}$ to $\frac{3}{4}$ of an inch from the edge of the articular cartilage. If it comes out less than $\frac{1}{2}$ inch from the edge of the articular cartilage, there is a chance for recurrence of the dislocation, because the tendon will not check the arm in extreme abduction. If fixed in the bicipital groove the tendon will not check the arm until it reaches from 255 to 280 degrees of abduction. This amount of abduction cannot be reached without dislocating the shoulder. The maximum abduction of a normal shoulder is 90 degrees and, combined with the scapular movement, the abduction of the shoulder reaches a maximum of 180 degrees.

6 The gouge is then withdrawn and the loose bone marrow is removed from its cavity. The gouge is reinserted and a flexible probe is passed through the tunnel from the proximal end guided by the gouge. The probe is threaded with the black silk which is attached to the proximal part of the divided tendon. The tendon is drawn through the tunnel and united to the distal part by means of the black silk which was passed through the tendon before it was divided.

7 The arm is abducted to a right angle and the transverse humeral ligament is sutured to that part of the tendon of the long head of the biceps which lies in the bicipital groove. This does two things: (1) It insures enough tendon from the head of the humerus to the glenoid cavity, thus removing any restriction of normal abduction and (2) it holds the tendon from moving up and down in the tunnel, and hastens its fixation in the tunnel.

8. The transverse humeral ligament and the capsule are sewed with continuous No. 1 plain catgut sutures the split deltoid muscle, with a

¹Nicola, Toufick. Recurrent anterior dislocation of the shoulder. A new operation. J Bone & Joint Surg 1929, 11, 1142.

Presented in the 29th exposition on the Treatment of Fractures, before the Clinical Congress of the American College of Surgeons, Boston, October 15, 1934.

few interrupted sutures. In women the skin is closed with skin clips or a subcuticular stitch.

9. The shoulder is then put up in a simple Velpeau bandage, reinforced with adhesive plaster with the arm close to the chest and the elbow flexed to 45 degrees. This position is maintained for 2 weeks. In epileptics it is wise to keep the shoulder immobilized for at least 6 weeks. If the operator chooses, the shoulder may be put up in the abducted position of 90 degrees, in a plaster of paris shoulder spica bandage. In 27 consecutive cases operated upon by the author the simple Velpeau bandage was used with excellent results.

10. The after-care may include radiant heat, massage and active movement, with the arm carried in a sling between treatments. In 9 of the 27 cases no physical therapy treatment was used. These patients made excellent recoveries with no prolongation of the convalescent period which ranged from 4 to 12 weeks. The 12 week convalescent period is to be ascribed to 3 compensation cases.

To date 37 cases have been done by the author with one recurrence. This recurrence was in a young man, who 5 months after the operation took a position as a camp counselor and caught a 10-pound medicine ball with his hands over his head. He felt something slip in his shoulder. I

believe that in this case the tendon slipped in the hole which passed through the head of the humerus. The tendon was not firmly fixed in the bone, and according to the operative note the synovial membrane surrounding the tendon was not removed. This should be done in every case to insure fixation of the tendon in the head of the humerus.

Three cases of recurrence of the dislocation have been reported to the author by various surgeons who have used this operation. In 2 of these cases the operator operated again. In one case the hole in the head of the humerus was too large, allowing the tendon to move up and down in the tunnel, thereby causing it to fray. In the other case the hole was not placed far enough on the articular surface of the humerus to check the head when the arm reached 180 degrees of abduction. These recurrences were due, therefore, to faulty technique.

CONCLUSION

The operation described can be used in all cases of recurrent dislocation of the shoulder whether the pathology be bony capsular or muscular. It is simple to perform, and leaves practically no restriction of motion. The convalescent period is short.

CONFERENCE ON TRAUMATIC SURGERY

INDUSTRIAL MEDICINE AND TRAUMATIC SURGERY¹

FREDERIC A. BESLEY M.D., F.A.C.S. WAUKEGAN ILLINOIS

IT would appear that there is an ever increasing interest in this important subject of medicine and surgery in industry, and we take pride in believing that the educational program of the American College of Surgeons is a basic factor in this attitude. This is consistent with all of the broad educational policies of the College which have builded this organization into such a strong institution of learning, that it is comparable to a university in its influence which has made for better medicine and surgery for the patient.

It is clearly established that the executives in industry are becoming aware of the potentialities for financial gain through the scientific prevention and remedial measures applied to the care of the workers in industry.

The survey work of Dr. M. N. Newquist and Dr. E. W. Williamson upon which they have reported and upon which they will make further contributions, has shown some interesting facts, and it is gratifying to note the desire on the part of industrialists to secure the approval of the College for their medical organizations.

The policy of establishing a minimum standard by which the efficiency of medical organizations in industry can be measured, and approved when deserving is analogous to the standardization of hospitals which has resulted in that great advancement in the proficiency in the care of the patient which is recognized as one of the outstanding accomplishments of the College.

Insurance carriers who assume the financial responsibility for many industrial organizations, under the workmen's compensation laws, are likewise showing a keen interest in the activities of the College and are beginning to manifest an understanding of the financial importance of securing the most scientific and approved care for the injured. The question of financing the general medical care of the workers in industry is still paramount, and fortunately it is receiving broad consideration from many groups.

The Medical Service Board of the College has done an excellent piece of work in the formulation of their recommendations. It is believed that the

influence of their report will be most important in bringing about some readjustment in methods of payment which will enable the individual of moderate income to budget against the unexpected costs of illnesses of himself and his family. Obviously, the resultant sense of financial and of health security will be conducive to greater happiness and contentment.

The Board on Industrial Medicine and Traumatic Surgery has recently been enlarged by the Board of Regents, and it is our purpose to arrange for geographical groups through which more intensive activities may be carried on in given localities. The work of these groups will be correlated through the secretary at the central office. The influence of the sectional meetings as they are arranged by the College is recognized as most important and at these meetings there is evidence of a broad interest in the questions involved in the applications of medicine and surgery in industry. Obviously these meetings are splendid forums for the dissemination of the knowledge that we are acquiring and may we urge the Fellows of the College to take advantage of these opportunities to promote discussions of all phases of this important subject.

The formation of a committee of consultants in each hospital, the function of which is to have general supervision of the methods of treatment for all traumatic cases, is meeting with very satisfactory success and is doing much to improve the end results, because of the more approved and scientific treatment that is rendered. This work is being carried on by the hospital department and the increasing number of institutions adopting this plan is due to the energetic efforts of Dr. Malcolm T. MacEachern, who never loses an opportunity to promote the best interest of the hospital patient.

It is recognized that this whole subject of industrial medicine and traumatic surgery has many problems and many angles including educational features, financial questions, and, most important, the health, happiness, and contentment of the worker. Social unrest and radicalism is brought about by discontent. Healthy minds and sound

¹Presented at the Conference on Industrial Medicine and Traumatic Surgery during the Clinical Congress of the American College of Surgeons, Boston, October 12-19, 1934.

bodies are most essential in producing contentment. What could be more conducive to health in individuals by and large than the intelligent care of the mass of workers in industry? We pledge our best efforts to this end believing that we are loyally supported by every Fellow of the

College, without whose sanction and aid we could accomplish little.

May I express my appreciation of the efficient work done by our secretary Dr. Bowman Crowell, head of the Department of Clinical Research, who makes it possible for this work to go forward

THE PROGRAM OF THE AMERICAN COLLEGE OF SURGEONS IN INDUSTRIAL MEDICINE AND TRAUMATIC SURGERY¹

FRANKLIN H. MARTIN, M.D., F.A.C.S., CHICAGO, ILLINOIS

THE Board on Industrial Medicine and Traumatic Surgery had its genesis during the World War. Traditions and theories were ruthlessly cast aside. It was necessary to execute tasks expeditiously and efficiently and with the greatest economy of management, money and man power. It was advantageous to the government to develop every facility that would preserve health. Hence a committee on industrial medicine was organized by the Medical Section of the Council of National Defense. Thus government planning and control demonstrated the economic and life-conserving value of a cooperative program such as the American College of Surgeons is putting into effect as a voluntary measure.

In a word, this program demonstrated as never before that the employer and the employee could accomplish most if they worked together harmoniously. The great leaders of industry of labor and of insurance composed their differences, to the great benefit of all concerned. This war experience was a progenitor of the Board under whose auspices this conference is being held.

In 1922 Dr. Daniel Z. Dunott convinced the Association of Railway Executives that railway employees would receive the most efficient care in hospitals approved by the American College of Surgeons. Forthwith by proclamation to the railroads, this association suggested that the employees of railroads so far as possible and practicable, should be treated in approved hospitals.

At the organization meeting of the Board on Industrial Medicine and Traumatic Surgery held during the Montreal Clinical Congress in 1926 an important first principle was recognized. The leaders of industry of labor of the insurance and indemnity companies, and of compensation commissions must harmonize their interests. And it is an outstanding slogan of the College that if we can convince the heads of these groups we will

be assured of the full, unqualified co-operation of assistants and associates.

The chairman of our Board, Dr. Frederic A. Beale, accompanied me to Washington on June 13, 1933 and we presented in detail the findings and accomplishments of the Board on Industrial Medicine and Traumatic Surgery to the head of the National Recovery Administration, General Hugh S. Johnson, and left with him an outline of a suggested code. His deputy administrator W. L. Allen, in charge of the hearings of the National Recovery Administration, read our suggestions, accepted them as a basis for consideration immediately dictated a suggested code covering our representations, and placed the two documents on file in his office for future reference.

A Minimum Standard for Medical Service in Industry has been perfected, and clinics which specialize in industrial medicine and traumatic surgery are under survey by the College to determine those which are equipped to give proper service. It is a stupendous task but with the support of the public—the employers and the employees—the economic saving will amount to millions of dollars, many lives will be spared, and thousands of potential cripples will be restored to perfect health. Leaders in industry have shown a deep interest in the basic study by the College of this important and far reaching problem. Obviously this is important for it furnishes the impetus for raising standards. Already 622 industrial establishments in the United States have complied with the minimum standard.

It is extremely important that all preventable health and accident hazards in industry shall be eliminated but it is likewise essential that diseases and injuries shall be properly diagnosed and treated. First and foremost, this will insure proper care to the ill or injured employee, and it will form the basis upon which diseases and disabilities may be reliably interpreted.

The liaison which has been established by the College between these various interested factors, and a knowledge of every circumstance which

surrounds the care of the ill and injured in industry, has placed the College in a position to aid in bringing about these beneficial, far reaching results.

A FOUR YEARS' SURVEY OF MEDICINE AND SURGERY IN INDUSTRY¹

M. N. NEWQUIST M.D., CHICAGO, ILLINOIS

DURING the past 4 years the medical departments or services of 1,122 industrial establishments have been personally surveyed by the American College of Surgeons. Of this number the medical services of 622 establishments, or 55 per cent of the total, have complied with the minimum standard for medical service in industry as formulated by the College and have been granted approval. I am pleased to report that in conducting these surveys, the College has received splendid co-operation from industry.

The campaign of the College to elevate the standards for medical service in industry is not only the practical application of its minimum standard for such service but it also represents a continuous study of the merits and defects of the various industrial medical services now in operation, in order that the data so compiled may eventuate in the proper constructive and remedial measures. The good features of the various medical services studied warrant recognition but they will take care of themselves. Let us first consider some of the defects which have been elicited by these surveys.

Defects in medical service in industry The major defect observed was that of inadequate medical or surgical supervision of health measures for employees and of sanitation of the plants. The provision of adequate medical and surgical service in industry today requires more than the skillful repair of industrial injuries. This is an age of prevention and the best way to deal with occupational diseases and industrial injuries is to prevent them. Medical supervision is absolutely necessary in order to secure adequate preventive health measures. Moreover, physicians and surgeons should be more than medical or surgical employees. By virtue of their qualifications they should be authorized to direct medical and surgical policies and procedures in the industrial establishments served by them. Adequate medical supervision will insure, first, adequate first aid and hospital facilities, second the elimination or reduction of accident and health hazards, and

third, the treatment of the ill and injured in industry by competent hands.

Inadequate medical supervision leads to inadequate medical service and it is largely for this reason that the College could grant approval to only 55 per cent of the medical services surveyed. During the past summer the College found in one industrial community alone over 90,000 employees who had been given so called pre-employment physical examinations by laymen. During the World War 7,000,000 men under 40 years of age were examined physically by medical examiners and 2,500,000 were found to be physically unfit for military service. The strenuous nature of military service naturally predetermines the rigid physical requirements which lead to the high percentage of rejections. In industry however, opportunity is presented whereby many of those afflicted with physical defects may be safely allocated to jobs that will make them self-supporting. In giving physical examinations to the army in industry, a trained medical examiner is the only one who is qualified to determine physical fitness for work. The solution of the problem connected with this situation is self-evident.

The records of pre-employment and periodic physical examinations of employees should be considered privileged communications subject of course to due process of law and as such they should be kept under medical responsibility and supervision. Only through the efforts of the unbiased physician or surgeon who guards the health and welfare of the employees as well as the interests of the employer, can these examinations and records be of mutual and of greatest value. Adoption of this principle will do much to reduce the opposition on the part of employees toward such examinations.

Surveys by the College have further revealed that in some industrial establishments nurses and first aid men are engaged in surgical procedures such as the suturing of lacerations. This practice on the part of industry is not only unsafe for the injured employee but it is illegal. The require-

¹Presented in the Conference on Industrial Medicine and Traumatic Surgery during the Clinical Congress of the American College of Surgeons, Boston, October 13-15, 1934.

ment by all states of a license for the privilege to practice surgery should automatically prohibit such practices by laymen.

The free examination of eyes of workers in industrial plants for the purpose of selling glasses has been observed to be a common practice carried on by commercial optical companies and by optometrists with the consent of the employers. The underlying commercial motivation of such service overshadows the benefits that might be expected therefrom. The College, through its minimum standard, has definitely gone on record as opposing the examination of eyes by any other than a qualified medical practitioner.

Finally, it has been observed that on account of inadequate medical supervision a number of industrial organizations have failed to institute recognized preventive health measures. In many instances this failure is due to the fact that the plant physician or surgeon has not been endowed by the official management with the appropriate authority to enable him to exercise properly his prerogatives. Of 925 plants recently surveyed by the College, only 7 per cent of the smaller plants had medical supervision of sanitation and general health measures as compared to 49 per cent of the plants having over 1,000 employees.

Rank of the medical departments in industry. The medical department should be an independent department co-operating with other departments within the organization but responsible only to a major official. In 925 industrial establishments included in our surveys, the plant physician was responsible to the personnel director in 41 per cent of the plants, to a major executive in 39 per cent, to the plant manager or superintendent in 17 per cent, and to the insurance carrier in 13 per cent. Most of the smaller industrial establishments have delegated the responsibility for the provision of medical service to the insurance carrier. Since our surveys to date have included comparatively few of the smaller plants, the percentage stated above relative to the insurance carrier should in reality be considerably higher.

Accident statistics. The National Safety Council has reported the following accident statistics for the United States for the year 1933:

Accidental deaths	90,000
Non-fatal disabling injuries	8,730,000
Occupational fatalities	14,500
Non-fatal disabling occupational injuries	1,555,000
Automobile fatalities	31,000
Non-fatal automobile injuries	1,685,000

That organization has further reported that the frequency rate of industrial injuries declined 58.8

per cent from 1926 to 1933 and the severity rate 39.4 per cent. Proper credit should be given to the rôle played by good medical and surgical service in this reduction. Investigation has revealed that an efficient medical and surgical service can be responsible for at least one-third of the reduction in the injury rates, while the safety service can be responsible for approximately two-thirds.

Studies made by the College have further shown that it is cheaper to pay for good medical service than to pay for disabilities. In a recent analysis of 334 industrial establishments, it was found that the smaller companies whose medical services were considered to be generally inadequate, had 39 per cent greater compensation costs than the larger companies where adequate medical service had generally been provided.

Workmen's compensation laws. All states have workmen's compensation laws with the exception of Arkansas, Mississippi, South Carolina, and Florida. During the past 4 years there has been a fortunate legislative trend toward the liberalization of the medical benefits for injured workmen. Several states have increased the medical benefits as to periods and amounts by amendments to their laws, while in some states the industrial commissions have arbitrarily liberalized the surgical fee schedule.

Eighteen states have state fund compensation insurance systems—Oklahoma having established such a fund in 1933. Twelve states have compensation laws covering occupational diseases either by a schedule of diseases or by blanket coverage. It is highly probable that many more states will make provisions for occupational disease coverage in their compensation laws within the near future.

CONCLUSIONS

In this presentation we have stressed the importance of the administrative or supervisory phase which is necessary in the provision of any industrial medical and surgical service. Industry is not handicapped by a lack of skilled physicians and surgeons in the country. Unfortunately however industry does not always provide the skilled medical and surgical service that is or could be made available. For this reason we urge those who are qualified in the field of industrial medicine and traumatic surgery to "chart the course" for industry so that the ethical standards and efficiency of its medical and surgical service may be such as to warrant the respect and co-operation of industry, of labor and the medical profession.

THE VALUE OF AN ORGANIZED MEDICAL SERVICE IN AN INDUSTRIAL ESTABLISHMENT¹

H. L. FERGUSON *Newport News, Virginia*
President, Newport News Shipbuilding and Dry Dock Company

THE acceptance of the invitation to address the Conference on Industrial Medicine and Traumatic Surgery on 'The Value of an Organized Medical Service in an Industrial Establishment' was prompted by the author's years of experience in the shipbuilding and ship repairing industry. This industry makes use of practically all the trades common to heavy construction work, in addition to many peculiar to its own held. It employs the common laborer as well as the highly skilled mechanic. The opportunity to reduce its mechanical processes to a safe and standard routine is limited on account of frequent situations presenting new and unusual problems. The physical demands on the worker are heavy and the work generally is above the average in its hazards. It is doubtful if there is any other industry in which an organized medical service is more needed and its value more apparent.

In these days of high labor costs, management is impressed with the importance of the selection of the physically fit to insure productive capacity of a high order and of the reduction of all forms of waste to a minimum including the waste due to illness and injury of workers. Without a capable medical service, the management of a company cannot succeed in its attempt to establish and maintain these policies. Organized medical departments are the outgrowth of a long and real need for better service to the sick and injured in industry. Surveys of various medical departments have revealed the fact that compliance with the compensation law does not in itself signify an efficient medical service and further that financial awards cannot offset a disability that is chargeable to inadequate medical service.

As a result of these findings the American College of Surgeons has created what is termed a Minimum Standard for Industrial Medicine, which standard embodies the essential features for providing an adequate medical and surgical service. Compliance therewith will serve the best interests of the employer and the employee.

The objectives of our medical department are to learn by examination, the physical and mental fitness of new employees, to know work requirements and hazards in order to facilitate proper placement of workers to maintain and improve

the health and efficiency of those already employed to educate the worker in accident prevention and personal hygiene, and to reduce lost time and absenteeism due to illness or injury.

No medical examiner should be considered competent to render a physical examination with recommendations for placement in an industrial establishment until he has a working knowledge of plant activities, job requirements, and hazards. The task of examining new employees and deciding their physical fitness and their place in our company rests upon a graduate physician who has performed this work during the past 6 years. These pre-employment physical examinations, when made by a competent physician carry with them a safety element in that applicants are rejected who if employed, would be a menace to themselves to fellow employees, or to property. They are a direct benefit to the applicant in that they call attention to any remediable defect and further assist in placing the employee in the position for which he is best fitted.

The maintenance and improvement of the health and efficiency of those already employed is an objective that in its practical application works a great benefit to both employer and employee. The periodical health audit is the one most powerful factor that can be put into operation to attain this objective. There can be no controversy over the statement that in practically all instances the efficiency of a workman all other circumstances being equal, increases with his sense of well being. In connection with the attainment of this objective we believe that it is not only necessary to have capable physicians, but quite as important to have a capable nursing staff. Graduate female nurses are generally used in the clinics of the larger industrial organizations. By virtue of their training they are familiar with the principles of asepsis and antiseptics, they have knowledge of bandaging, they are already well trained in keeping records, they keep the clinic in a splendid state of cleanliness, and, finally, the white uniform has its psychological effect. These nurses command the respect of the employees, the kind, quiet manner in which they handle the sick and injured explains why there is no difficulty at our plant in having employees report to the medical department.

The education of the employee in accident prevention and personal hygiene is accomplished only by persistent effort. Coincident with the pre-employment physical examination our new employee is given a pamphlet, and he is directed to read it. This pamphlet includes many safety measures which in most instances, cause the reader to begin to think along safety lines. We employ a full-time safety engineer and an assistant safety engineer who work in close co-operation with the medical department and the industrial departments. Careful observation over a period of years is convincing us that 90 per cent of all accidents are caused by carelessness either on the part of the injured man or on the part of some other individual. Continuous efforts are directed toward making the plant a safe place in which to work. A spirit of competition has been built up between the various departments in an effort to reduce both the number and the severity of accidents. Records of the number of accidents per million hour working period and the degree of severity of accidents show conclusively that efforts made to teach men how to accomplish their work in a safe manner and efforts directed to make materials and machinery safe for men to work with, do bring about results. There is no end to a safety campaign. The personnel of industry is ever changing, the new man does not know so much about the dangers, and the old man has heard so much about them he is likely to become careless.

The reduction of lost time and absenteeism due to illness and injury is the most striking result from the activities of the well organized medical department. The frequency and severity rates are a fair index to the efficiency of the medical service. In many cases the safety of an injured man lies in the hands of the one rendering first aid. The duration of the period of convalescence frequently is in inverse proportion to the degree of thoroughness and correctness with which the injury is first treated.

It has been estimated that the prevention of infection alone would reduce the time lost from all ordinary causes by at least one third. It is obvious that the larger companies owe much of their excellent accomplishment to the fact that their organized medical services have kept the minor injuries from becoming major ones. This is accomplished in our plant by insisting that the employee report to the medical department with any injury no matter how trivial it may seem to him.

Accidents are not the only source of loss which involve medical service. It has been generally accepted that illness causes eight times as much absenteeism as accidents. The protection of the

employee against smallpox by vaccination, the administration of typhoid prophylaxis, are measures which by their institution promptly reduce the number of lost hours.

We believe the lost hours from injury and illness can be greatly reduced by real co-operation between the various departments in any plant. We have brought to a practical minimum the number of disgruntled patients by encouraging them to get back into the old stride as soon as possible, frequently giving them the simplest kind of work at the start.

Surveys show that many of the larger industrial organizations provide excellent medical service for their employees, but that much can be done to improve the service especially in the smaller industrial establishments. This comparative inadequacy is due as a rule not to a lack of skilled physicians or surgeons in the community but rather to a failure on the part of the smaller companies to provide early medical supervision and service and to select only competent physicians. The practical solution of this problem is the definite organization of a plan for medical service which will locate responsibility in competent medical hands. The most important step is the choice of a competent chief surgeon. Managements must choose men of ability of high ethical standards and if possible men with better than average personality. After this choice has been made the operation and choice of the remaining personnel of the department may be left entirely to the chief surgeon and the department will reach its greatest efficiency.

The personnel of our medical department is as follows: chief surgeon, assistant chief surgeon, 1 consulting eye, ear, nose and throat specialist, 1 consulting dentist, 3 graduate nurses, 1 secretary, 2 colored orderlies.

The equipment of our clinic consists generally of the following: operating room, X-ray room including a shock-proof X-ray with all fluoroscopic attachments, developing room and fire-proof storage space for filing films, dressing room, completely equipped physiotherapy department, 2 ambulances.

The records of the medical department are of invaluable assistance in placing and transferring employees and in determining when they should be retired from active service.

A well organized medical department in the plant performs a service over and above the saving of expense for it prevents the injured employee from getting into the hands of unscrupulous or incompetent lawyers and doctors, enabling the employee to retain all of his compensation, and

makes him better satisfied with his work and employer

The reports of insurance companies show that the medical expense for an injured employee is increasing tremendously resulting in higher insurance rates. A proper medical department in the plant is able to hold such an expense down to the minimum, as such a department is keenly interested in getting the injured man back on his job as soon as possible.

We have found after an experience of many years that it pays to have a properly organized and equipped medical department as an integral part of our organization. In fact, when operating under normal conditions with from 5,000 to 6,000 men, we believe that it more than pays for itself in reducing accidents, illness and lost time. In my judgment, it also results in the promotion of good will and a mutual protective interest between employer and employee

COME OVER INTO MACEDONIA AND HELP US¹

G. L. MARSTON BOSTON MASSACHUSETTS

Vice-President and General Claims Manager American Mutual Liability Insurance Company

MY title is a sudden inspiration, possibly reflecting a phase of a subject in which I have been vitally interested for many years. I could perhaps as well have captioned my talk, "Why are we not getting better end results in our industrial injuries?" I presume that a title of any address is more or less necessary if for no other reason than that it keeps one's listeners busy trying to connect the subject as announced with the discourse as delivered. I hope, however that my few remarks will be less of a discourse and more of a heart-to-heart talk on a subject in which we are all greatly interested.

It may be wise for me to state that I appear before you not only as a representative of my company but perhaps as an ambassador of good will without portfolio and representing the casualty insurance business as a whole. However that may be, time did not permit my securing authority from my associates of our Claims Executives' Committee to speak officially for them, yet I feel certain that nothing I shall say would not be heartily accepted by them.

For a little more than a decade we have been struggling to improve the administration and procedure of the most ambitious piece of social legislation ever enacted a system of compensating the workers in industry who might be injured without regard to the question of fault. The statutes relative thereto are known as workmen's compensation laws. Among the many provisions of these laws are the sections relating to medical care and the expense incident thereto. These medical provisions have many angles and the time allotted me will permit of only briefly alluding to one or two of these angles.

During the first years of our experience under the workmen's compensation laws, we found accumulating on our books a surprisingly large number of cases classified as permanent totals. A study of these cases revealed all too many of them as falling within the class of what you would call poor end results. What was the cause? What was the trouble? It is the speaker's personal opinion that this situation was due in large measure to the fact that it was almost impossible to interest the better grade of surgeon in industrial work. In considering this matter we must in fairness to all concerned bear in mind that in those days we were all dealing with a new problem and too much blame cannot be attached to anyone for the mistakes that were made.

A great deal has been accomplished but there is yet much room for improvement. The American College of Surgeons undoubtedly met with a considerable opposition from members of the medical profession when they set out by education to improve the standards of fracture service. Undoubtedly there was resistance also to the program of the College in respect to the standardization of hospitals, but notwithstanding that opposition such hospitals anxiously await the announcement from your College indicating whether or not they are upon the approved list. Is it beyond the realm of possibility that the College may some time in the not too distant future establish also suitable standards of qualifications which those who would practice in the field of industrial surgery must meet? Is it not possible that the College may even designate those upon whom they will set the seal of their approval as qualified to handle industrial injuries and act as

advisors? Your Board of Industrial Medicine and Traumatic Surgery under the able leadership of Dr. Beasley has established a minimum standard of medical service in industry which we heartily approve.

You have probably noted in your programs or in the public press an announcement by Dr. Beasley giving a skeleton outline of a program which has resulted from a conference held in New York between representatives of your College, headed by Dr. Martin Dr. Beasley and Dr. Newquist and the Claims Executives Committee of the National Council on Compensation Insurance, together with their medical directors. If carried out this program will mean a higher standard of surgery in the treatment of industrial injuries than we have ever known before. It will mean an earlier return to work of the injured man and a reduction of lost time and wages; the consequent reduction in compensation losses will lessen what is becoming almost an intolerable burden to industry—the amount of premiums paid, which after all reflects the losses. This, I believe is going to mean much not only to the injured man but to all the groups interested in the administration of the workmen's compensation law: the members of the medical profession as represented by your membership here, the industrial accident boards and commissions, as well as labor.

I wonder if you men have any idea of the tremendous sums that are expended every year for medical and hospital service. According to the report prepared by the National Council on Compensation Insurance, dated March 10, 1933, the compensation carriers represented in the National Council pay approximately forty million dollars annually for medical and hospital service, of which approximately six million goes to hospitals and thirty-four million is paid to doctors. A study of the medical cost trend from 1920 to 1929 shows an increase in the average cost per compensable case from \$77.00 to \$103.00; these figures being based on the experience of all carriers in all states over that period. These figures would be nothing to weep over if there had been a corresponding reduction in the compensation losses.

In a report of a special Committee of Claims Executives of the National Council who had given careful study to the question of the constantly increasing medical and hospital costs, it was found that much of the difficulty was due to the "treatment by unqualified physicians and surgeons, ending in poor surgical results, with prolonged disability and extended medical treatment over

treatment, including physiotherapy; padded bills; additional cost and inconvenience in transferring cases to specialists; and it was their opinion that the principal cure for this situation could be summarized briefly in the word education—education, first, of the injured; second, of physicians and surgeons and hospitals; and third, of industrial accident boards and commissions.

The importance of the physician in the whole scheme of compensation has perhaps never been fully appreciated. Not only does the physician receive directly approximately one-third of all compensation costs, many millions in amount as we have just indicated, but he is also largely responsible for the size of the other two-thirds. The rates of compensation, the schedules and benefits are fixed by law. Industrial accident boards and commissions can only apply the mathematics to the facts as they find them. It is the doctor who in the last analysis determines what the loss is both to the employee and to the employer. His skill determines the period of recovery and the extent of the recovery—in other words the end-result.

His conscientiousness and fairness determine the liability of the employer and the insurer. He is the great variable factor in this whole scheme and in this connection I come to the last thought that I want to leave with you and that is a situation which should have the serious consideration, not only of this body but of all state and county medical associations. I refer to the giving of evidence at hearings before industrial accident boards and commissions by men upon whom has been conferred the degree of doctor of medicine and who have been licensed by the state to practice as such—evidence which is neither scientifically reasonable nor scientifically probable. Such men are not only trailing in the dust the fair name of their profession but are dishonorably influencing awards by their false testimony.

May there be a better understanding between the members of your profession and the representatives of the casualty insurance business. Too frequently local groups on one side of the fence or the other (there should be no fence) antagonize each other by statements which do not reflect the real situation. The business of insurance has never been unfriendly to the medical profession.

It is the hope of the business of insurance that the vision which appeared to the Apostle Paul may appear to the Fellows of this great College and they may bear the words and answer the call "Come over into Macedonia and help us."

PAPILLOMA AND CARCINOMA OF THE BLADDER AMONG DYE WORKERS¹

G. H. GEHRMANN, M.D., F.A.C.P., WILMINGTON, DELAWARE
Medical Director E. I. du Pont de Nemours & Company, Inc.

THE so called aniline tumor of the bladder is an entirely new occupational disease in this country, the first cases appeared in 1931, and the first report on a group of cases was made by Ferguson, Washburn, Anderson, Gay and myself. Since this first report (1) further studies by this same group with the very able assistance of Dr. E. E. Evans and Dr. Humphrey D. Wolfe, have materially increased the data on cases under observation and treatment.

Before presenting this later group I will very briefly review a few of the earlier investigations and attempt to give you a short description of the general nature of the dye manufacturing industry.

In 1895, Rehn reported the first observations made on a group of 45 men engaged in the dye industry in Germany. At that time he reported 3 cases of papilloma and 1 of carcinoma, and suggested the possibility of occupational origin. In 1904 he reported 20 additional cases.

Leutenberger in 1912 reported 18 cases which he had observed at Basel, and at the same time he reported, as a result of studying the statistics of the Basel Clinic, that 50 per cent of all bladder tumors treated at the clinic were among dye workers. Further, he proved that the incidence of bladder tumors was 33 times greater among dye workers than among those outside the industry.

Rehn's original theory brought about a great deal of discussion, much dissension and lengthy investigation. However his original opinion eventually became an undisputed fact. Bladder tumors were accepted as an occupational disease and made compensable in Germany.

Prior to 1914, practically the entire dye manufacturing industry was confined to Germany and Switzerland. Subsequent to 1914 the industry was developed in this country and has since grown to major proportions.

Briefly the manufacturing process may be divided into 3 stages, viz. chemical, intermediate, and dye. The first stage is a distillation process, and from the coal tar there is derived benzol, toluol, xylol and naphthalene. In the second, or intermediate stage, the products of the first stage are subjected to the processes of nitration, chlorination, reduction and sulphonation. In the third and final stage the dyes are compounded. It is in the second or intermediate stage that bladder

tumors develop and in no instance have they occurred in the first or third stages.

Since 1931, we have made 1,601 cystoscopic examinations and of this number there have been 1,173 individuals examined. 428 of the examinations have been rechecks. This entire group has been engaged in the manufacture of dye intermediates.

In this group we have found a total of 49 tumors, 35 of which are papillomata and 14 carcinomata. Thus, we have an incidence of bladder tumor in 4.1 per cent of the group examined. Deaths from cancer of the bladder as recorded in the United States Registration Area from 1925 to 1929 were 3.20 per cent (2). We have no figures indicating the incidence of bladder tumors in 1,173 individuals outside of the dye industries who have had routine cystoscopic examinations.

ETIOLOGY

The tumor producing chemicals are encountered in the intermediate stage of manufacture. A careful analysis of our group indicates that beta naphthylamine, benzidine and alpha naphthylamine are the causative materials. In Germany beta naphthylamine, benzidine, and aniline are accepted as the principal irritants. We have repeatedly examined a group exposed to aniline only for as long as 18 years, finding no tumor incidence, and therefore it seems possible that aniline is at least a questionable factor. English dye manufacturers have reported several cases from alpha naphthylamine and we can confirm this observation with a group of 12. The final observations have not been made and eventually other chemicals may be added to the list, but we can say that up to the present time beta naphthylamine, benzidine, alpha naphthylamine and possibly aniline are the causative agents.

Length of exposure varies from 5 to 23 years, the average being 11 years. German observers have reported 1 case in as short a time as 2 years. This case, however, is questionable, since there is no evidence to indicate that this man had a normal bladder when engaged for work.

Age does not seem to bear any direct relation ship to incidence. In our group the age range was 1 case 24 years of age, 9 from 30 to 40, 13 from 40 to 50 and 12 from 50 to 60.

Family history of cancer seems to be no factor for we were able to obtain a positive history in only 5 of our cases.

Absorption takes place by 3 routes: the respiratory, gastro-intestinal and skin. The most important route is undoubtedly the respiratory but it must be remembered that skin absorption of intermediates can under conditions of careless handling become the most important portal of entry. Further in view of the fact that tumor production is due to long continued exposure to low concentrations, even the gastro-intestinal tract may assume important proportions. One of the most important facts to remember is that after a minimum exposure of 2 years removal from occupation does not change the possibility of tumor development. Tumors have developed from 5 to 35 years after change of occupation.

PATHOLOGY

The pathological anatomy is essentially the same as in tumors of unknown origin. Tumors may occur as primary papillomata or may be malignant from the beginning. They may be single, multiple, papillary, sessile, infiltrating or non-infiltrating. The majority occur in or near the trigone, but may occur anywhere in the bladder wall. Metastasis is rare and in our group has not been observed.

SYMPTOMS

There are no reliable symptoms, either objective or subjective, to be ascertained without actually viewing the tumor through the cystoscope. Hematuria is a late symptom and often does not appear until malignancy is well advanced. Simple tumors may or may not show microscopical or macroscopical blood in the urine. Our routine requires a cystoscopic examination—of intermediate employees once a year while employed every 3 months in those cases which have been positive for tumor and prior to employment in all cases. German observers rely upon the presence of blood in the urine on 3 successive occasions to determine the necessity for cystoscopic examination. Our experience has convinced us that with this method many early cases progress into the advanced stages before detection. Many papillomata become carcinomata, and carcinomata may reach the stage where complete resection of the bladder is necessary with transplantation of the ureters.

TREATMENT

Treatment is divided into two divisions—preventive, and treatment of the tumors.

Preventive. The manufacture of dye interme-

diates must be conducted in such a manner as to absolutely exclude dust, fumes and skin contact. This means the adoption of an entirely closed process for the manufacture of alpha and beta naphthylamine, benzidine and aniline.

All applicants for employment in or about these processes must have a cystoscopic examination and before acceptance must present a normal genito-urinary system.

Treatment of tumors. Tumors classified as Grade I which are small and easily accessible are treated by bipolar fulguration through the cystoscope. Large tumors of the Grade I type are treated by open operation.

Tumors of the Grade II type, which are reasonably small and easily accessible are treated through the cystoscope by fulguration. Large and inaccessible tumors are treated by open operation.

All tumors of Grade III or IV are treated by open operation and implantation of radon seeds.

Our experience has convinced us that large tumors which are apparently benign may upon biopsy show sections which are definitely malignant. Furthermore, every tumor of the bladder can be considered malignant until proved otherwise by biopsy and microscopic examination.

The treatment as outlined is that which we have followed in the past 3 years. We have had only 2 fatalities, 1 case developing an acute retention 3 months subsequent to operation and the other developing a rectovesical fistula. The remaining patients are all back at work with the exception of one who was operated upon about 3 weeks ago.

SUMMARY

1. Bladder tumor is an occupational disease occurring among dye manufacturing workmen who are exposed to certain intermediates.

2. Time of exposure and not age is the causative factor.

3. Cystoscopic examination is the only sure method of diagnosis.

4. An absolutely closed method of manufacture will prevent tumor formation.

5. All tumors should be detected as early as possible and destroyed immediately.

BACK INJURIES¹

FREDERIC JAY COTTON M.D., F.A.C.S. BOSTON MASSACHUSETTS

BACK strain is a subject one hesitates to speak on, so cumbered is it with difficulties in diagnosis, with wild theories of pathology and with divers methods of therapeutic procedure. The fact is that, save for certain specific lesions, we know very little about backs—hardly enough even to draw the line between pathological conditions and those due to actual trauma or continued slight overstrain. We can name certain definite pathological cases, such as the Strumpell Marie type with ankylosed vertebral bodies, and the infectious type with progressive fusion of sacro-iliac articulations, in which trauma is an exciting and not a producing cause. Similarly, spondylolisthesis or pedicle defects indicate no recent cause although they may be a source of aggravation.

In definite traumatic cases there is no question about the fractures, whether they be of the unimportant transverse process or of the vertebral bodies, for they are of recent origin. However, the differentiation between an old compression fracture and the occupational wedge-shaped body (Lane) or changes sometimes seen in elderly patients with hypertrophic changes, is a source of argument.

The occurrence of lumbosacral lesions without pedicle defect or spondylolisthesis is debatable, as are also many sacro-iliac cases. It must be confessed that our diagnosis between lumbosacral and sacro-iliac lesions is clinically far from being precise.

There are sacro-iliac cases obviously involving displacement, usually in flexion that are not shown in the X ray, but in which brilliant results from manipulation leave no diagnostic doubt. In all other lumbosacral and sacro-iliac cases, unless secondary changes such as porosis or cartilage absorption are evident we have no proofs—and as a result we are often wrong in our diagnosis. There are elaborately worked out tests for differentiation but they do not seem to work out very well. Perhaps to clear the decks, we should consider the lesions as to which we have actual data.

First let us consider fractures and that means compression fractures from the tenth dorsal to the second lumbar vertebrae. These fractures show clinical localization of symptoms even if there is no obvious deformity. The skiagraph is—in fresh cases—unmistakable.

Treatment is under question only as to whether we should attempt forcible correction of the compressed vertebra or not. With or without this treatment we must attain hyperextension and hold it. Bed treatment for a month followed by a brace and the indicated exercises usually results in a cure in 6 to 9 months. These patients do almost uniformly well if they are so treated.

Fractures of transverse processes often multiple, seem to be usually the result of convulsive muscle action and are in themselves unimportant. Union often by fibrous union only. They seem to be only a complication and a visible evidence of a badly wrenched back.

Rupture of cartilages, now talked of, does occur. How important it is is doubtful, but for the next year or two this lesion with the migration of the much advertised nucleus pulposus will possibly make much legal trouble. How important it is clinically is *sub judice*.

There is no doubt that lumbosacral lesions are overlooked. Congenital lesions, whether full-blown spondylolisthesis or pedicle defect only may give no trouble for youth and early manhood, but may make trouble after trauma. These lesions and few others call for spinal fusion. The difficulty is to make a diagnosis and that depends on excellent X rays. In absence of this definite diagnosis indiscriminate fusion operations are not called for, whereas they have frequently done much harm.

Similarly fusion operations higher up can be justified only by very definite local signs indicating ligament tear or damage to articulations or the like which are seldom definitely shown. Lately we have heard more than a bit about asymmetry of articular facets and the resulting strain.

Most of the back cases seem to be strains of muscle or ligament, tending to hang along lame for months. If treated with absolute bed rest in case there is irritative spasm, and with brace support for a few weeks then with careful exercise following this, most of them will get well. In some cases there is a toxic background calling for the search for foci of infection.

Commonly enough there is an actual pathological arthritis of infectious type. Frequently there is an obvious overgrowth—"hypertrophic arthritis"—which is in fact hardly more than the badge of age or hard work. While the latter condition does not always determine a bad prognosis it does

give a poorer slower comeback after trauma.

Very rarely there are sacro-iliac joints that crunch in and out of place. These are the cases, perhaps the only ones, calling for fusion. There are others in which careful history taking and examination leave no doubt of a displacement, usually in a position of flexion. These are the cases for reduction by extension manipulation. When treated, they do as well for us as for the osteopath and furnish spectacular cures. They cannot be diagnosed by X-ray.

As to other sacro-iliac conditions the picture is very confusing. Cases showing the so called clinical signs evidence no displacement, and if there is a pathological condition present it is apt to be one of porosis about the joint or later sclerosis

more suggestive of arthritic change than of trauma.

Acute cases, apparently sacro-iliac conditions with referred sciatic pains, often with exaggerated muscle spasm, yield with fair constancy to rest in hyperextension, belt support, and careful exercises. What the pathology is we do not know. It seems that the more radical measures of fusion of various sorts have shown no encouraging results.

Knowing as little as we do of the pathology of the usual strains, it is well to proceed conservatively unless an actual diagnosis indicates otherwise. After all, many back injuries fall in the category of what our colored brother calls "mishery in de back" and they do well if they are not over diagnosed and overtreated.

RECONSTRUCTION SURGERY—THE REPAIR OF SUPERFICIAL INJURIES¹

SIR HAROLD GILLIES, C.B.E., F.R.C.S., F.A.C.S. (HON) LONDON ENGLAND

Plastic Surgeon to St. Bartholomew's Hospital, London, the London County Council, the Royal Air Force, St. Andrew's Hospital, Dollis Hill, London, and the North Staffordshire Royal Infirmary, Newcastle-under-Lyme

AS under the term of reconstructive surgery almost any form of plastic surgery other than cosmetic might be included, the subject would require a complete treatise to do it justice and as it is one's experience, whether good or bad which might be of some use to the profession, it is proposed to base this paper on personal experience. All surgery is reconstructive, even though its main primary object at the time be destructive.

CLASSIFICATION

Group 1 Many general surgical operations are plastic in character but a true plastic operation may be defined as one in which new tissue either in the form of a graft or flap is introduced.

Group 2 Many cases of injury to the face are typified by a displacement of normal tissues without true loss of substance, such as in broken noses and jaws. In this group the main treatment consists in reduction of the fracture, and replacement of the soft tissues and only in the severer cases is a graft required. It is obvious that accidents of work, transport, and home life are likely to produce injuries falling under Groups 1 and 2.

Group 3 Those 'plastic' or cosmetic operations which involve reduction of existing normal tissues or additions to them are definitely in a different category and may on this occasion be dismissed.

THE CAUSATIVE AGENCIES AND THEIR RELATIVE FREQUENCY

Group 1 cases require the introduction of new tissue by means of a graft or flap. Burns form the chief causative agent of the injuries, and those occurring in the home are still the most prevalent—clothes catching fire, scalds, hot water bottle burns and burns acquired during epileptic seizures being the most frequent. Other common causes are burns due to the explosion of spirit and paraffin lamps, to the ignition of celluloid combs, and the explosion of petrol due to static electricity during the dry-cleaning of clothes. Burns associated with other injuries resulting from accidents in motor cars, motor cycles, motor boats, and aeroplanes are only too prevalent. The accidental explosion of acids in chemical works, criminal

cases of acid throwing and gunshot injuries both accidental and intentional are causes sometimes met with. The electric burn not infrequent, presents distinctive features. Industrial injuries other than those resulting from burns include crushing by machinery and scalping accidents now less frequent since hair has become shorter, and inspectors more vigilant. Mining accidents from falls and explosion must also be included. Large losses of the skin of the face and body may occur as the result of road accidents. Injuries to the eye, apart from the eyelids occur as the result of flying pieces of hot metal or acid, and fragments of glass, these may cause ulceration of the conjunctiva and subsequent symblepharon.

Injuries of the face causing displacement of normal tissue, *Group 2*, are most frequently the result of accidents of transport. Soft tissues are cut, crushed, and displaced while the bony and cartilaginous framework of the face may be fractured and displaced by these very common injuries. A large number of these displacement injuries also occur as the result of sports, such as boxing, football, cricket, riding, polo, hunting, skating, aviation hockey, lacrosse and even golf. The same type of injury may also occur, but less frequently, in the factory and the home.

DIAGNOSIS

For a successful outcome of the treatment, an accurate diagnosis must be made. This point is emphasized because few surgeons have been trained to estimate by eye the exact loss of skin, muscle, bone or cartilage that may occur, or indeed the amount of displacement of normal tissues. But it is on these very points that the diagnosis for the reconstruction mainly rests. Further, loss cannot accurately be estimated until allowance has been made for the replacement into normal position of those parts that are normal but displaced.

TREATMENT PLAN

Having made this estimate one must then decide on the best method of repair, and if the method of choice be not available which of the various alternative methods should be attempted in any individual case, taking into consideration the age, sex, physical, and financial condition of

TABLE I—FREE GRAFTS

Type (Fig. Nos.)	Donor area	Recipient area	Method	Author's references
<p>Skin grafts</p> <p>Thin rasor grafts are generally taken from the inner side of the arm where it is hairless (Thiersch grafts) (Fig. 7)</p>	These grafts are generally taken from the inner side of the arm where it is hairless	Thin rasor grafts are usually used in places where mucous membrane is normally present, as in the mouth, eyelid, buccal sulcus, or cutaneous grafts for contracted sockets in the eyelids	Instruments used, Blair or Thiersch knife, stretched, heated and vaso-line, the heated blade used to keep the skin at even stretch. The graft is cut as thinly as possible. Graft applied on "stret" model with pressure	1, 2, 3
Thick rasor grafts	The inner side of the arm or any aspect of the thigh or back. Immense pieces of graft can be cut with Blair or Thiersch knife	The most common conditions in which these grafts are used are granulating areas of the scalp and forehead, ocular and retroperiorbital ectropion of the eyelids, V-ray burns of the face and neck, and loss of whole skin on the body or limbs. They are particularly applicable for replacement of skin on the hands, for webbed fingers, X-ray and other burns	Same as for thin except that the graft is cut considerably thicker. Graft applied on stret model with pressure	10
Detached grafts (eyelid thickness grafts)	The inner side of the arm, front of the chest, outer aspect of the thigh, the back of the ear and upper eyelid	Eyelids, and portions of the face in which good cosmetic effect is specially worth attempting. When successful, they are more flexible and of better texture than rasor grafts, but the percentage of perfect success is not as great as with the thick rasor grafts. Indications for use where there is ocular ectropion of one eyelid, and not of the opposite eyelid, enough skin may be successfully freed to repair the ectropion eyelid. Skin from the back of the ear can usually be obtained, and is useful for eyelids, loss of skin on the nose, and other small patches on the face	The skin is excised in horizontal dissection, down to, but not including, the fat. The graft is cut to such size and shape that when it is sutured into place it will be at the tension of normal skin—as other words, as exact fit. Pressure applied	
<p>Hair-bearing grafts</p> <p>There are also detached grafts. Care must be taken to include all the hair follicles</p> <p>Patch grafts</p> <p>Mucous membrane grafts</p>	<p>The mastoid strip</p> <p>The thigh</p> <p>The mucous membrane of the lower lip and inside of the cheek</p>	<p>For eyebrows and mustache</p> <p>On granulating wounds where cosmetic effect is not imperative</p> <p>In cases are almost entirely caused by loss of connective tissue, when there is normal epidermis, and particularly in symphysis to form the lining of new eyelids. They also may be used in the eyelids</p>	These grafts are usually detached, but may be skinned with a rasor. They are usually cut to the size of the part to be replaced and sutured in place. Even the thinnest skin graft is likely to grow sufficient hair to replace an existing eye	4
Fat grafts	Fat is usually obtained from the abdominal wall, and frequently from the area of an existing scar. The fatty firm will not bulk be absorbed on grafting	The commonest application of fat method is for bulking up the contour of the cheeks or chin, or for injection beneath previously implanted skin graft. They may also be used under depressed scars	A piece of fat is cut to the shape required and about 30 per cent larger than finally required to fill the defect to allow for shrinkage. It is then inserted underneath the depression	5
Cartilage grafts (Figs 8 and 9)	<p>(1) Costal cartilage. The free border of the seventh rib is usually taken, as it is the thickest and straightest possible</p> <p>(2) Septal and alar cartilages and the cartilage of the concha may of great use for minor deformities of the nose</p>	<p>Chinify the bridge of the nose</p> <p><i>Remable.</i> A curved piece of ear cartilage may be used to give support to a new skin nose, or new eyelid. Large pieces of ear cartilage may be utilized to give form to a new ear, but this type of graft usually has to be taken from donor</p>		6
Osteochondral grafts	The portions of the base and cartilage in the rib may be utilized with success to form new bridge in the nose, the bony portion being sutured to the freshened bony portions of the existing nasal bridge	Generally of value in young children's noses. Osteochondral grafts may be used to replace the premaxillary ridges of the body of the nose after surgical removal of that area, the cartilaginous portion, inserting into the glacial cavity region and forming a false point there		
Bone grafts	Usually the ilium	This is the usual method of repairing new bone in the maxilla, though block ilial grafts have also been used. Osteoperiosteal grafts from the tibia have also been used with success in making a new mandible		

*Cases will occur from time to time in which completely detached portions of the face, and fingers or feet, in particular, are brought up with the patient, having been retained and carefully preserved in the hope that the doctor might be able to reattach the portions. From a strictly logical standpoint of the type of case, it is very definitely recommended to attempt the reattaching. The illustrations are appended of an extreme case in which the tip of the nose was cut off by a piece of glass and sutured back into place 10 hours later. In a dog bite case portions retained and sutured from the dog or the ground were reattached, successfully enough to obviate further treatment, in the third, large portions of the forehead and eyebrows with frontal sinuses were sutured back, but was complete failure. Advice: Keep the pieces

Fig. 1 Thin razor graft on mold, for eye socket.

the patient. Thus the very young and very old are not suitable for large and complicated flaps. As the forehead skin provides the best type of replacement tissue for any part of the face other than the eyelids, it should be used more readily in the female, who can cover the secondary blemish with her hair, than in the male who can not do so. Further, the female must often be spared the additional scarring of a pectoral or arm flap when a belly flap is equally available. The male can tolerate a low neck or chest disfigurement with equanimity in order to have a facial blemish restored with healthy skin. The presence or absence of hair must also be taken into account as between the sexes. Both the local and general physical condition should be gauged, the local from the point of view of vitality and infection, and the general from all points of view, not for getting the psychological. Finally the financial status enters the problem, and a decision to carry out a presumably inferior method of repair may have to be taken in order to shorten the stay in hospital and the number of operative stages.

It cannot but be admitted that this decision as to method of treatment is one of the most troublous that can face either surgeon or physician. Should the ideal be attempted with a considerable risk? Should the next best be carried out with less risk? Or should an inferior result be aimed at

Fig. 2. Loss of whole thickness of skin over bridge of nose. Left, immediately after loss; right, after replacement of piece of skin which had been preserved and was sutured into the nose 10 hours after accident.

with hardly any risk? Not only should a careful balance sheet be prepared of the pros and cons of the particular problem, but the surgeon's own predilections and experience must also be taken into consideration. Frequently it is almost impossible to state beforehand that the inferior method will always produce the inferior result, or the more troublesome superior method a perfect result. It is therefore frequently necessary to tell the patient to try the less-likely-to-be-successful method leaving the possibly more complicated and brilliant repair as the last resort. By such a decision a surgeon will often deny both his patient and himself the satisfaction that each deserves. We therefore return to the cardinal principle of medicine and surgery, namely, that the patient, not the condition, must be treated. In this respect it should not be forgotten that the psychological outlook of the particular individual will modify the treatment plan.

However, in order to have a basis for arriving at one's decision, the accompanying tables of repair by free and pedicle grafts have been prepared. They are admittedly most incomplete, and savor of that dogmatism which should be absent from the reconstructive surgeon's mind: the guarded use of opportunism is an essential factor in plastic surgery.

METHODS OF REPAIR

The cases may be divided into two groups. In Group 1 the repair is accomplished by the introduction of new tissue. In Group 2 by replacement of displaced tissue. In Group 1 free grafts and flaps are used in the repair. By an autologous or free graft is meant the transplantation of a completely detached portion of the body and its reapplication to another. In surface wounds when function and form are desirable the whole

of the contracting scar or granulating area should be excised prior to the application of the graft. Surface grafts may, however, be definitely applied to clean granulating areas by one or other of the methods. The functional and æsthetic results depend on so many factors that no purpose would be served by a detailed description of them. Of the various grafts mentioned in Tables I and II, all are uniformly successful except perhaps the whole thickness skin graft and the mucous mem-

Fig. 5. Industrial accident. Partial scalping. Repair by single pedicle flap. Note the secondary wound was successfully closed by suturing in the scarred epithelium which was removed to accommodate the hairy flap.

brane graft nevertheless one must bear in mind that there is still a great deal of experimental work to be done in connection with all forms of grafting.

The Group 2 cases, in which the repair is accomplished by replacement of displaced tissues include defects (A) soft tissue injuries and (B) fractures and dislocations.

A, 1 *Uncomplicated scars* The repair of simple scars might hardly be included under "reconstruction surgery," but an occasion may always arise when even if the scars have healed well by first intention or after a primary suture, the result is displeasing and the possibilities of excision and re-suture have to be considered.

Three main points may be stressed. The final repair should not be undertaken before all inflammation has subsided. Lymphatic obstruction

should be lessened by skilled massage, and the vascularization of scars increased. The value of the pre-operative and postoperative X-ray or radium treatment, by a skilled therapist, of keloid scars should be borne in mind.

The primary scar or scars, may then be etched together with all the underlying scar tissue, dirt, and foreign bodies. In these operations as in all plastic work, tissue trauma caused by the use of heavy instruments, or the clumsy use of light ones should be avoided. Hemostasis is important, haematoma being a serious complication. There is no contra-indication to the use of fine catgut ligatures, but with superficial vessels direct crushing is satisfactory. After complete undermining, the skin edges may be brought into accurate apposition, and in clean straight incisions one fine subcuticular silk worm gut stitch threaded

on an eyeless needle may be used. These stitches have the advantage of not passing through the skin edges except at the end and commencement of the incision. In certain cases ordinary interrupted stitches on eyeless needles are indicated. These interrupted stitches may be left in from 2 to 4 days the subcuticular longer, and protection may be afforded by a light gauze dressing applied with even pressure by mastisol or elastoplast fixation. As regards the postoperative care, the patient can improve these scars by self massage with sterile paraffin (Fig. 10)

A. 2 *Complicated scars* One would include in this section irregular Y shaped U-shaped, and depressed scars. The same principles are involved in their repair as in that of uncomplicated scars. There is frequently cicatricial contraction affecting the surrounding structures, and when released a gap is left which must be replaced by a simple advancement or transposed flap. During the suture of these flaps, care must be taken to ensure that they have a sufficient blood supply, and when re-sutured they should be under tension as

HAND INFECTIONS IN INDUSTRIAL ACCIDENTS¹

ALLEN B. KANAVEL, M.D. F.A.C.S. CHICAGO, ILLINOIS

VARYING with the industry as shown by insurance statistics, hand infections still are responsible for from 5 to 9 per cent of all total disabilities. Were it not for these startling percentages I would not presume to discuss with this body of surgeons, whose primary interest has been the care of industrial accidents, some of the simple principles of surgery of the hand in relation to infections. Of the total hand disabilities 20 to 50 per cent arise from infections, a large proportion of these having their inception in trivial injuries. This number can be markedly reduced by a more widespread appreciation of the potential danger, a more intense campaign of education of the employee as to the importance of caring for simple injuries, of employers as to the economic value of prompt and efficient treatment, and of the profession as to the basic principles of diagnosis and treatment.

Certain etiological factors that should always be borne in mind have a peculiar application to industry. Employees as a rule live an indoor life, have little sunlight and often poor food. They are therefore debilitated and favorable subjects for the spread of infections. In cold climates we see this most often in the late fall or early spring, and in warm climates after the intense heat of the summer. During these periods the danger of virulent infections is increased especially in the freezing and melting period, due to the prevalence of influenza, tonsillitis, and similar infections with resultant streptococcal contamination of the blood stream.

Another factor is the ignorance on the part of employees that leads to primary inefficient or even harmful treatment such as neglect and fellow employees' treatment of simple injuries, as for instance the removal of splinters. It must also be admitted that too often the attending surgeon who would be vitally interested in a major injury, pays too little attention to these small injuries, especially in the follow up.

Again employees are peculiarly liable to trauma of the hands and to cracked calluses, both of which are fruitful sources of infections.

It has been found that certain types of infection are peculiar to certain industries. For example, confectioners, who handle fermenting fruits and spray them with sugar, and cooks and bartenders, who deal with fermenting grain and vegetables, are peculiarly liable to paronychia. In such cases

the nail loses its luster, turns dark, and is finally lost. A persistent chronic inflammation of the nail bed continues for weeks and months. If the cause is recognized and the occupation changed or if rubber gloves are worn the condition heals promptly. The surgeon caring for the patient has not done his duty until he has apprised the employer of the danger and taken steps to prevent the infection in other employees.

Office workers not infrequently accidentally break off pieces of indelible pencil which lodge in the skin. Ill advised attempts to remove the soft lead end in breaking it and fragments are left. The presence of these fragments results in local necrosis with chronic recurring local infection. In such cases the imbedded pencil parts should be removed by incision. If left until necrosis begins, the necrotic area including the fragments should be excised. We have had an exceptionally large number of severe infections in nurses due to inadvertent pricking of the finger with pins.

A type of infection not often recognized is that found among those who milk cows or tend cattle—the so called milker's nodule. The infection is caused by cattle hair entering a crack in the skin or being introduced at the time of an injury. Cattle hair has spines placed obliquely to the hair—somewhat like pineapple spines—and these hairs tend to work deeper into the tissue instead of being expelled as usually happens with foreign bodies. A local recurring infection that may last many months results and will not clear up until the hair is removed.

In the treatment of hand injuries, we have in our clinic come to rely on the meticulous application of certain procedures which we believe to be important—some of these are often neglected.

Severe injuries are treated promptly, hence infection does not often occur. If it does occur adequate drainage is provided. Any disability resulting is generally due to the primary injury or loss of tissue. The converse is true of the trivial injury.

In severe injuries we avoid primary antiseptic treatment, cleansing the wound only with soap and water unless grease is present, when some solvent is also used. We are also strongly in favor of debridement and primary closure of the wound if the treatment has been prompt. We also suture the tendons and nerves at this time if we do not fear infection. Where some hours have elapsed

or we fear infection we favor leaving the wound partly open for drainage, and do not suture tendons and nerves. If no infection ensues at the end of 48 hours we close such wounds and reopen after healing for the suture of the tendons and nerves.

Gas bacillus infections are the cause of too many fatalities due primarily to lack of careful observation and prompt treatment, and also to the fact that too much emphasis has been placed on the terminal picture of crepitation and evidence of gas spreading in the tissue. The time for the injection of gas bacillus antitoxin is either immediately as a prophylactic measure in those cases in which dirt contaminated with animal excreta is ground into the wound or in the incipient stages of the infection. If we wait until widespread crepitation is present or until gas can be demonstrated by X ray we have waited too long. The only way to avoid fatal delay is constant vigilance in any case not having an uneventful recovery. A sweetish peculiar odor may be present, but of more importance is the escape of two to a half dozen bubbles of gas as seen when the wound is dressed.

When we come to the question of treatment of the ordinary simple injury, the factors that have militated against prompt recovery are often found in the neglect of proper primary treatment. Such neglect may be due to the desire on the part of the patient to continue work, to the disinclination of the surgeon to place the patient on disability pay, to failure to realize that trivial injuries more often than lacerated wounds lead to loss of life and permanent disability, and finally to lack of knowledge or failure of application of the basic principles of treatment. Immediate treatment in the way of forcing out a drop of blood in punctured wounds, prompt removal of splinters and the application of an antiseptic such as iodine when immediate clean surgery is not available will do much to lessen the incidence of infections. Our essential line of defense must be the local and general resistance of the patient.

In both severe and trivial injuries a factor often lost sight of is that rest of the part by immobilization is of primary importance and in case there is any tendency of the infection to spread, the patient should be in bed. May I emphasize the importance of immobilization. It helps to prevent the spread of infection, aids in local healing and is too often neglected. We see too many ambulatory patients with simple non-immobilizing dressings favoring prolonged healing. Even injuries in the neighborhood of joints are often not immobilized. Again surgeons too often forget that if the infected hand is treated with the fingers extended,

ankylosis with permanent disability may ensue, even though the infection is controlled. I cannot emphasize too strongly that immobilization whether by simple splint or voluminous hot dressings should always be so applied as to place the hand in the position of function. A large percentage of the disability now seen following simple injuries could, we believe, have been avoided by adherence to this simple rule. Also we have seen nothing to change our opinion that in case of doubt or the demonstrated presence of infection voluminous hot moist dressing up to the shoulder is of great aid. Koch has recently drawn attention to the experimental work of Hudack and McMaster demonstrating the spread through the lymphatics of dyes within 30 seconds after injection. Without doubt bacteria spread from the site of the punctured wounds with almost the same rapidity. Therefore any incisions in non localized spreading infections, except in phlegmonous erysipelas or gas infections, will not only do no good but will be positively harmful.

Another simple truth, lack of knowledge of which has cost insurance companies much and entailed prolonged disability for the patient, is that where we see long continued suppuration in the hand there is in all probability necrosing tendon or devitalized bone requiring adequate surgical procedures.

There are many other factors that lack of time prevents me from considering. Among them may be mentioned the wide and not evident injury to tissue in the electrical burn, the lack of appreciation of the peculiar anatomy of the metacarpophalangeal joint and its relation to prolonged infection.

For the same reason I cannot discuss the peculiar anatomy of the hand, the sites of predilection for pus, the normal channels of extension or the general principles of diagnosis. Information as to these matters is available to those who desire it. However, I must emphasize that the most fruitful source of death and disability arises from the surgeon's failure to differentiate lymphangitis from suppurative tenosynovitis. The diagnosis is difficult but not impossible. The suffused redness, more general edema and often red lines of lymphatic infection in lymphangitis are sharply contrasted with the symmetrical enlargement of one finger, great in comparison with the associated edema of the others, tenderness sharply outlined by the anatomical outline of the tendon sheath most marked at the proximal end and pain most marked at the same point on extension of the finger. In suppurative tenosynovitis serve to differentiate the two.

Failure to differentiate them may lead to an ill advised incision in lymphangitis with not infrequent unnecessary complications and death or on the other hand delay in drainage of the tendon sheath may result in loss of the tendon and prolonged convalescence. Most of the deaths we have seen have been due to ill advised incisions in lymphangitis and the greatest proportion of severe disabilities have had their origin in suppurative tenosynovitis in which drainage had not been promptly instituted.

Finally may I discuss some of the broader aspects of the question. While adequate education of employees and employer has been established in many of our large industries, there is still much to be done. Every surgeon having responsibility for the care of any plant no matter how small should not consider his duty done when he has cared for the injured man. He should analyze his accident cases as to the causes and immediately take steps to prevent a recurrence.

He should establish such co-operation with plant managers as will permit his intimate knowledge of conditions about the plant that may favor injuries or infections.

The casualty companies check carefully as to elevator weakness, explosive mixtures, open machines, and similar evidences of gross negligence but too often no one checks the plant for the source of common simple injuries and I doubt if any one but the doctor can do this. Each plant is a problem in itself. Wire ends on boxes, exposed fragments of tin, splinters on buns, pins on packages and projecting nails cost the insurance companies a score of times more for disability expense than do elevator accidents.

In a certain plant Mock noticed that minor scratches with subsequent infection were often due to the lining of buns that had become splintered by use. The department manager was warned and in one year the injuries from this source were reduced 86 per cent.

Employees and foremen should be educated by lectures and posters of the dangers and have knowledge of the procedures immediately necessary in case of accident. Fellow employees help with splinters should be avoided and the employee taught to see the doctor or nurse, or failing these to apply iodine at once.

Employers and insurance companies should be educated as to the financial saving by prompt treatment and early hospitalization in case of doubt. This latter is of vital importance. Deaths and morbidity arising from infections following

simple injuries in a majority of cases occur in ambulatory cases. Mock reports that in 250 serious cases treated by ambulatory methods 83 per cent required incisions, and in 150 serious cases treated with prompt hospitalization only 53 per cent required incisions.

This emphasizes not alone that hospitalization is important but also that the surgeon should arrange for an adequate follow-up of his simple injuries so that he may know not tomorrow but immediately if infection is developing and be able to institute prompt and efficient treatment. Such close follow-up except in few instances, is now seldom instituted.

There are 4 parties interested in an industrial accident—the employee, the insurance company, the employer and the doctor. The employee's interest is in the patient himself and his compensation, the insurance company's in economic factors and the employer's and doctor's, in both. This quadrilateral interest has led to some confusion, misunderstanding and not infrequently to inadequate care. Each party has felt its interests might be jeopardized and has fought against imposition. I need not elaborate upon malingerers of the patient, the pressure of insurance companies to cut legitimate charges with its consequent temptation to padded service and fees, the difficulty of convincing insurance companies and employers that a larger primary expense for prompt hospitalization and efficient treatment is cheaper in the end, the inefficiency of service when the patient and the insurance company each feel their interests are opposed and act accordingly. The doctor cannot serve two masters when each demands a different service.

In reality however I am convinced that each party is willing to do his part. All wish efficient service and it is the doctor who by giving it can harmonize the divergent attitudes. I venture the assertion that if the industrial surgeon will give a more imaginative service, will assume the responsibilities I have mentioned, not alone treat his patient, but by adequate analysis find the frequent causes of such accidents in any given plant and take steps to prevent them, will institute personal plant investigation with recommendations as to how accidents may be prevented, and will foster educational programs designed to lessen the consequences if they occur, not alone will accidents and infections be lessened but many of the social and economic difficulties causing friction between the 4 groups interested will disappear.

OPHTHALMOLOGY AND OTOLARYNGOLOGY

VASCULAR CHANGES IN THE RETINA¹

ARTHUR J. BEDFORD, M.D. ALBANY, NEW YORK

A SERIES of original photographs of the ocular fundus were presented and a demonstration was given of several variations from the normal in the blood supply of the retina. The fact that mere tortuosity of the retinal vessels is in itself not a sign of disease was emphasized. Diseases affecting the blood vessel walls can be promptly recognized by early changes in transparency. This was well portrayed in the pictures of cases with patches of sclerosis and in others of extensive atheroma. The sudden occlusion of the central retinal artery—so called embolism—was also illustrated and discussed, and the rapid

closure of the central retinal vein—so called thrombosis—was described with the aid of several slides. The demonstration of the circulation in and about the macula included arteriosclerotic changes in the retinal and also in the underlying choroidal vessels. Due emphasis was laid upon the impossibility of definitely diagnosing optic nerve lesions simply by the color of the disk. The value of stereoscopic fundus photographs was emphasized; they afford the most exact and earliest evidence of fundus changes including the optic nerve expression of intracranial disease.

SIMPLIFICATION OF PROCEDURE IN PLASTIC SURGERY ABOUT THE EYES¹

JOHN M. WHEELER, M.D. F.A.C.S. NEW YORK, NEW YORK

THERE is a tendency for plastic surgeons to think complexly, plan complexly and operate elaborately. The simpler plastic procedures can be made, the better. Whenever it is possible detached grafts should be used for repair of the eyelids. Whenever possible skin of the upper lids should be used for grafting on the lower eyelid, or skin of one upper eyelid should be used for grafting on the other upper eyelid. Full thickness skin devoid of underlying tissue should be used. In case of severe ectropion, if the upper lids are involved, skin epithelium can be used for most cases, and epidermis without true skin taken from the lateral aspect of the thigh is the tissue of preference. For lining a newly constructed socket, skin epithelium (epidermis) without any true skin is best. If only epidermis is taken there will be no hairs and no glands, and so no secretion. The 'Thiersch graft' contains connective tissue and it is not appropriate for socket lining. Best results are obtained by exci-

sion of particles of old conjunctiva, which may give annoying secretion. If the socket is completely lined with epidermis, it will be clean, except for a little exfoliated epithelium, which is easily removed from the skin-lined socket.

There is no need for the surgeon to use pedunculated grafts in the reconstruction of an obliterated socket. Rarely, pedunculated grafts have to be used in reconstruction of the eyelids. For substitute eyelashes strips from the lower part of the brows can be transplanted. These do not have to be pedunculated. For obliterating false passages between skin surface and nasal cavity pedunculated flaps from the upper lid should be used. These should be lined with skin epithelium a few weeks before the pedunculated flaps are turned into place. The lining should accurately fit the opening and it should be free from hairs. For restoration of brows skin from the occipital scalp serves fairly well. Pedicles are not necessary.

Abstract of paper presented before the Section on Ophthalmology, Clinical Congress of the American College of Surgeons, Boston, October 6, 1934.

CLINICAL STUDIES IN SLIT LAMP OPHTHALMOSCOPY¹

JONAS S. FRIEDENWALD M.D. F.A.C.S. BALTIMORE, MARYLAND

From The Wilmer Ophthalmological Institute of the Johns Hopkins University and Medical School

THE slit-lamp ophthalmoscope is an instrument which combines the highest attainable clarity in the ophthalmoscopic image with the possibility of oblique focal illumination of the posterior segment of the eyeball. The advantages of oblique focal illumination for the examination of transparent and translucent media have been well known in ophthalmology for a long time, and the application of this principle in the development of the corneal

microscope has been a great clinical and scientific advantage. It is to be hoped that similar advantages may result from the application of the same principle to the examination of the posterior segment of the eye.

Lantern slides were presented which showed the appearance of the posterior portion of the vitreous, hyaloid membrane, retina, optic disc, and choroid in normal and various abnormal states.

INTRAVENOUS TREATMENT OF DISEASES OF THE UVEAL TRACT²

WILLIAM L. BENEDICT M.D. AND PAUL A. O'LEARY M.D., ROCHESTER, MINNESOTA

IT would appear from the clinical data so far assembled that the optimal time for commencement of treatment by gold salts in cases of iritis, indocyclitis, and scleritis is after subsidence of acute inflammation in the anterior segment of the globe. Before that stage we believe that other more effective remedies can be used. In any event, every means at our disposal for improvement of the patient's general health is employed.

Patients who improved under tuberculin therapy were not given gold salts. The selection of patients for intravenous administration of gold included many in whom clinical or biological evidence of active tuberculosis could not be demonstrated. Gold sodium thiosulphate is given intravenously in courses of approximately 20 injections. It is our practice to start with 10 milligrams and increase the amount slowly until the patient is receiving 50 milligrams twice a week, as the maximal dose. If

the patient shows the slightest sign of intolerance, use of the drug should be discontinued temporarily, and when its use is resumed the dose should be half of that which produced the reaction. We have found it advisable to prescribe a rest of 2 months following a course of 20 injections; a similar series of injections may then be repeated if the response has been inadequate.

The drug is poorly tolerated by the markedly debilitated patient, by one with advanced, active, febrile, pulmonary tuberculosis, and by patients with advanced hepatic or renal disease. For pregnant women the dose of the drug should be smaller by half than that ordinarily given. A reaction may appear immediately or be noted a considerable time after injection. Treatment thereafter should be cautious or should cease. Using this method of treatment in ophthalmological cases we have had no complications.

Abstract of paper presented before the Section on Ophthalmology, Clinical Congress of the American College of Surgeons, Boston, Oct. 19-21, 1934.

¹Because of lack of space, considerable important material has been omitted from this abstract. This material will be included in the author's reprints. Paper presented before Section on Ophthalmology, Clinical Congress of the American College of Surgeons, Boston, October 19, 1934.

THE CLOSURE OF THE CATARACT INCISION¹

CHARLES NELSON SPRATT M.D. F.A.C.S. MINNEAPOLIS, MINNESOTA

It is a well recognized surgical principle that, unless drainage is indicated, operative wounds should be sutured and not left for nature unaided to make the closure. Rapid healing is thus obtained, infection is avoided and the danger of postoperative hernia is reduced to a minimum. Incisions into the cranial cavity, abdomen, or thorax, are sutured. Why should an incision in the eye remain unsutured?

After the ordinary cataract section the edges of the wound tend to adhere. We all know however from past experience that such a closure is not free from complications such as delayed union, reopening of the wound by coughing and straining, downward growth of epithelium into the anterior chamber (Elschnig has demonstrated this) prolapse of iris, vitreous loss, expulsive hemorrhage and late infection.

The use of a suture after the cataract operation was suggested by Williams of Boston in 1867. Since then many modifications have been described, especially by Kalt in 1894 and Van Lint in 1911. The extraction of the lens beneath a bridge of conjunctiva was, according to Schweigger, suggested and used by Desmarres in 1851 and published in 1858.

Husain, in 1918 described a conjunctival flap method in which an opening in the anterior chamber was made with a keratome and the angles were enlarged with scissors. Holbrook Lowell of Boston reported, in 1920 a series of operations done after this method. A modification of this sutured pocket flap has given me the least number of operative and postoperative accidents. As the method has been described elsewhere (3) only a brief account is here given.

A horizontal incision, 15 to 20 millimeters long and 5 to 8 millimeters above the limbus, is made in the conjunctiva. This is dissected to the lumbus and down on each side with blunt scissors to nearly a level of a horizontal line, thus forming a deep pocket. A mattress suture of fine silk on a round needle is placed in the conjunctival edges and the loops of the suture are placed on each side so as to be out of the field of operation. A suture is placed in the superior rectus as suggested by Angulucci. Holding the flap of conjunctiva with blunt tissue forceps, thus securing a 2 point fixation, an incision is made at the lumbus and beneath the conjunctiva with a narrow Graef knife. If the incision is too far back, an iridectomy results if too far forward, a buttonhole is made in the conjunctiva. These accidents are to be avoided but an iridectomy is not objectionable and a buttonhole changes the operation to that generally done when no conjunctival flap is made. The anterior capsule is removed with tooth forceps. By holding the flap of conjunctiva forward, the

edges of the wound are separated and the lens is expressed with a spatula. If cortex or blood remain, the anterior chamber is irrigated. The suture is tied and the wound is secure.

The lens may be extracted, in this type of incision with forceps, by tumbling by traction by vacuum, or after a capsulotomy. The simple or combined extraction may be used and irrigation may be employed if indicated. During the delivery of the lens the traction on the conjunctival flap not only fixes the globe but also enlarges the wound and thus aids in the exit of the lens. There is less danger of vitreous prolapse than in the usual method when the two spoons are used the one to express the lens and the other to make a backward pressure on the scleral portion of the wound. In case vitreous

Fig. 1. Cataract extraction pocket-flap method. a, The incision in conjunctiva b, conjunctiva pocket made mattress suture in place, flap held up to secure fixation, knife beneath the conjunctiva for the puncture; c, counter puncture made, flap held down to secure visibility and to fix the globe; d, the incision completed at the limbus, the lens is expressed; e, wound is closed.

presents, the eye can be immediately closed without loss of contents, just as when loops of intestine present in an abdominal section. The opening in the globe is made in a clean field and thus the possibility of infection is reduced to a minimum.

This operation differs from other methods of suturing, as suggested by Williams (1867), Kalt (1894), Czermak (1903), Van Lint (1911) and other writers, in that there are no open angles to the wound and should prolapse of iris occur the latter is protected by the layer of conjunctiva. There is no danger of late separation of wound edges as the sutured flap is as firm in hours as the unsutured wound is in days. Delayed healing is thus avoided. The down-growth of epithelium into the incision and anterior chamber is not a possible complication since no epithelial margins are exposed, the incision being beneath the conjunctiva. The astigmatism is less after an incision of this kind than when the opening is made at the limbus or in the cornea. Convalescence is rapid and safe; most patients are out of bed the day after operation. The danger of late infection is reduced to a minimum.

The only objections to this operation are that there is lack of visibility; the operation is longer; the suture requires removal, and there is slightly more bleeding. The lack of visibility is more fancied than real. Three minutes increase in the time of operation saves days in bed and reduces the time of hospitalization by one-half. The removal of suture is necessary after any operation and needs little consideration. Bleeding into the anterior chamber is objectionable but not serious, as the hyphema is quickly absorbed.

with these one must possess a knowledge of broncho-pulmonary and oesophageal diseases, together with a general appreciation of chest diseases, in addition to experience with laryngological problems.

The untrained endoscopist who does an occasional bronchoscopy or oesophagoscopy has few successes to report; he subjects his patients to unjustifiable hazards. In no field of medicine do end-results bear such a definite relationship to training, skill, team work, and other factors. In foreign-body work the end-results are positive. Either the foreign body is or is not removed; but injury to the patient may convert an apparent success into a failure.

To the uninitiated certain foreign-body cases, notably coins or safety-pins in the cervical oesophagus, appear to be easy. Nothing could be more misleading. All foreign-body cases should be considered difficult since a certain degree of special training and skill are necessary for successful removal. The difficulty in removal seems to increase as the skill of the endoscopist decreases. Unfortunately the unskilled are often called in to handle emergency cases. These cases generally call for the highest degree of judgment and skill and should be undertaken only by one who is competent. It is far safer to do a diagnostic bronchoscopy in a case of suspected bronchiectasis than to attempt to remove a difficult foreign body from either air or food passages.

Any physician contemplating the practice of peroral endoscopy should prepare himself by special training under competent guidance until he has mastered the

ordinary technical difficulties. This should ultimately include a course of training on the living patient. In addition, he should be familiar with the practical clinical aspects of the subject. While much of this can be gained from medical literature, one's fundamental training should be supplemented with actual clinical experience. The matter of equipment is a common stumbling block. A careful selection of instruments is highly important, and one cannot economize on the essentials. Diameters of tubes and lengths of forceps must vary as do the anatomical measurements of air and food passages in infants, children, and adults. To attempt to pass an adult bronchoscope in a child bespeaks absolute ignorance of the fundamental principles of bronchoscopy. One should use tubes suited to the patient and the problem under consideration. This applies to all other instruments. The use of suitable equipment is fundamental in peroral endoscopy and is the only way to practice economy in saving human lives.

To summarize, peroral endoscopy in its broadest application is a field for the otolaryngologist. The scope of the work is as diversified as the diseases of the tracheobronchial tree and oesophagus are. A knowledge of the general medical aspects of these organs should be considered necessary. One engaging in peroral endoscopy should be thoroughly trained in the technical phases as well as the clinical application of the subject. An adequate physical equipment is indispensable.

THE RECOGNITION AND TREATMENT OF ONE TYPE OF MÉNIÈRE'S DISEASE¹

S. J. CROWE, M.D., F.A.C.S. BALTIMORE, MARYLAND

THE term Ménière's disease as used in this paper does not imply a hemorrhage into the inner ear but is descriptive of the symptoms. This paper describes the otological findings in 40 patients with Ménière's disease. The symptoms in each of these patients were (1) tinnitus—usually limited to one ear (2) impaired hearing—usually limited to one ear and (3) violent and sudden attacks of vertigo.

In 37 patients in this group the entire auditory nerve (cochlear and vestibular) was divided intracranially by Dr. Walter Dandy. In the 3 remaining patients only the vestibular nerve was divided. The intracranial division of the vestibular nerve without damage to the auditory or facial nerves has been successfully carried out on 10 additional patients since this paper was written. In every case the division of the vestibular nerve promptly stops the attacks of vertigo.

The etiology of the disease is unknown, but there are many factors which suggest that the lesion is not located in the cochlea but either in the nerves or the more central auditory and vestibular tracts. At any rate the division of the vestibular nerve, which severs the connection between the end-organs in the

semicircular canals and the central connections, will always stop the attacks of vertigo just as the division of the sensory root of the fifth nerve will stop attacks of trigeminal neuralgia.

The characteristic hearing defect in these patients with Ménière's disease is of the inner ear or nerve type. Air conduction is better than bone conduction and bone conduction is shortened or nil. In no case with attacks of vertigo was the deafness complete.

The semicircular canals on the affected side when tested with the caloric test are sometimes hyperactive, sometimes the response is normal and sometimes it is very subnormal or entirely absent. In our experience the results of vestibular tests are of little value in the diagnosis of this disease.

It is characteristic of Ménière's disease that there are remissions, or long intervals of several months or even years during which the patient is entirely free from the attacks of vertigo.

Intracranial division of the vestibular nerve on one side, or on both sides if necessary, is the treatment of choice, and in the last 13 cases this operation stopped the attacks of vertigo without further impairment of hearing.

¹Abstract of paper presented before the Section on Otolaryngology, Clinical Congress of American College of Surgeons, Boston, October 17, 1934.

THE DIAGNOSIS OF CHRONIC INFECTION OF THE TONSILS IN RELATION TO INDICATIONS FOR OPERATION IN CASES OF CHRONIC FOCAL INFECTION¹

GEORGE MORRISON COATES, A.B. M.D., F.A.C.S. PHILADELPHIA, PENNSYLVANIA

INTEREST in this subject has been revived by a number of symposia, held in England by the Fellowship of Medicine recently under the conduction of Tilley Glover McKenzie, and in this country by I. W. Dean at the 1934 meeting of the American Medical Association, by Kaiser Nissen and Mosher at the American Academy meeting and by the writer and William Gordon in the spring of 1934, before the Philadelphia County Medical Society.

Adverse criticism has been levelled at the profession because of the practice of indiscriminate removal of the tonsils.

To settle these questions, it is necessary to study carefully the clinical anatomy, the physiology and the histopathology of the tonsils, and correlate these with organic disease produced elsewhere. It is also necessary to define clearly what constitutes a diagnosis of tonsillar infection. It is generally accepted that the tonsils may act as a portal of infection for other parts of the body as well as constitute a primary cause for infectious processes of focal origin elsewhere in the body but it must not be forgotten that the infected tonsils may be only one of several such agents. Pemberton has shown that 50 per cent of a group of arthritics recovered or improved even in the presence of such a focus.

Often, removal of infected tonsils fails to give relief because other foci of infection that are present are overlooked. Thus foci may exist in the teeth, sinuses, ears, gall bladder, gastro-intestinal tract, prostate, etc. Often individuals may carry septic tonsils for years and show no evidence of disease processes elsewhere from this focus of infection because the resistive powers of the individual are great enough to counteract the toxins fed into the system from the tonsil infection. Any lowering of the resistance or increased virulence of the infection may upset this balance so that symptoms due to focal infection may manifest themselves.

Clinically the following points may be accepted as proper criteria for the diagnosis of septic tonsils, though some authorities may lay more stress on different individual points: the history of local tonsillar inflammation, acute or chronic. Hajek's dictum—repeated attacks of acute tonsillitis; one or more attacks of quinsy; repeated coryzas beginning with sore throats, soreness or discomfort in the tonsillar region; cervical adenitis (dental sepsis eliminated); enlargement or tenderness of the tonsil node at the angle of the jaw; gross hypertrophy of the tonsil, the anterior pillar having an inflamed, reddish or purplish hue, especially at the upper part. Liquid pus expressed from one or more crypts by

drawing the anterior pillar forward and outward and pushing behind the tonsil. Pus may be often found in the crypt of the upper pole. Aspiration may be useful. A tonsil that is firmly attached to its fossa suggests a previous quinsy; many attacks of acute infection, or a long process of chronic infection. Simple tonsillar hypertrophy with enlargement of the cryptal orifices often shows eventually small ulcero-congestive lesions at their borders. Bacteriological examination if a streptococcus is recoverable, is accepted by some as strong confirmation of other signs and symptoms. Caseous masses should place a tonsil under suspicion. At times these masses are accompanied by liquid pus. The masses themselves do not warrant tonsillectomy except for social reasons such as bad breath. Small purulent collections concealed in the crypts by inflammatory adhesions, often plainly seen, are diagnostic.

We cannot with any assurance say that a given tonsil is not infected unless it is proved so by bacteriological and pathological investigation after removal. How often do we see pus gushing from the crypts after applying the snare or guillotine to a fairly innocuous appearing tonsil?

Having made the diagnosis that a given tonsil is infected, we must decide whether it is actually causing damage or is likely to cause it in the future.

Regarding prophylaxis, opinions vary. Kaber states that prophylactic tonsillectomy did not make for great immunity to recurrent infections of the respiratory tract, to contagious disease or rheumatism. Horace Williams in the Philadelphia Hospital for Contagious Diseases showed conclusively that the children who had middle ear suppuration and complications almost without exception had not been tonsillectomized.

McKenzie doubts the value of statistics used to disprove the value of tonsillectomy. He asks whether the tonsils were completely removed, whether, in some cases, only adenoids were removed, or whether there were regrowths or recurrence of the lymphoid tissue.

Herbert Tilley states that a septic tonsil should be removed, but deprecates the wholesale removal of tonsils without a careful study of the case.

Tonsillar sepsis in relation to focal infection and distant pathological conditions requires the co-operative study and observation of the otolaryngologist and the attending physician. A connection between the infected tonsils and the distant disturbance should be proved if possible. The study should be extended to all parts of the body as insisted upon by Nissen. Close clinical observation over a considerable period of time by the physician

plus frequent reports of subjective symptoms by the patient are essential to determine the association between the local and systemic infection.

The diagnosis of tonsillar infection rests with the otolaryngologist, but the most careful and meticu-

lous study of the case as regards the relationships between the local and systemic infection will depend on co-operation on the part of the otolaryngologist with the attending pediatrician, internist or surgeon.

THE PRESENT STATUS OF INFECTION OF THE UPPER RESPIRATORY TRACT IN RELATION TO FOCAL INFECTION¹

WILLIAM V. MULLIN, M.D., F.A.C.S. CLEVELAND, OHIO
Cleveland Clinic

IN the evaluation of the importance of focal infection in various systemic diseases, careful study and rational judgment should replace illogical jumping at conclusions. Because a focus of infection is discovered does not mean that it is causing the patient's symptoms or that its removal will cure him. This may be coincidental.

The relative importance of the various foci of infection are as follows: teeth, tonsils, prostate, cervix, gastro-intestinal tract and sinuses. Absorption from teeth is more likely than from other foci because of their anatomical structure and the fact that the infection is well locked in. Tonsils are likely to be an important focus of infection and their removal is indicated often for prophylaxis even when no causal relationship can be demonstrated between the disease and the tonsillar infection. Sinuses are less likely to be a factor in focal infections, and their importance has been greatly overrated by some specialists. If there is infection of the sinuses, conservative treatment should always be used before operations, which perhaps are unnecessary are resorted to.

Among the diseases in which focal infection has been emphasized as a causative factor are infectious arthritis, rheumatic fever, chorea, valvular heart lesions, nephroses and nephritis, and hypertension. In my experience the removal of foci for nephroses

or hypertension is usually disappointing, but may be indicated in some cases for improving the general condition.

The removal of foci has not effected any improvement in hearing in cases of eighth nerve deafness, in my experience. Quite often, numerous fruitless operations are performed before the correct diagnosis of fifth nerve neuralgia is made.

Toxic labyrinthitis is one condition that has been definitely benefited by the removal of foci, and there are definite indications for tonsillar operations in eye conditions, such as iritis and inflammation of the uveal tract. In my opinion papilledema and neuritis of the optic nerve are not due to infection in the sinuses.

The warning is reiterated that operations for the removal of foci should be performed only after careful study of the patient and the correlation of all factors which are contributing to his illness. The fallacy that tonsillectomy is a panacea for all ills should be combated vigorously. That this warning is necessary is indicated by the numerous cases of congenital and advanced deafness I have seen in children on whom one or more operations have been done without benefit and yet no attention has been given to the things that might really help the patient, such as instruction in lip reading, hearing aids, etc.

THE CELLULAR CHARACTER OF ONE HUNDRED TEMPORAL BONES CLINICAL AND SURGICAL SIGNIFICANCE¹

EDWARD F. ZIEGELMAN M.D. F.A.C.S. SAN FRANCISCO, CALIFORNIA

THE embryological development, histological character and anatomical configuration of the temporal bone is of prime importance for a clear conception of its cellular system, the pathological changes it may undergo and proper therapeutic application. It is a composite structure composed of a squamosal and a petrosal portion, the former a flat bone, the latter a long bone. This gives it an individualism of its own. Within compact osseous walls is primarily diploetic tissue, which may be modified by age, biological factors, systemic disease or early infection in the middle ear cavity. Though the temporal bone contains the otic capsule with other important structures, the change that it may be subject to is one of bone pathology, and its surgical therapy should be based upon this principle, modified and altered to meet the special anatomy of that portion of the structure involved.

The apex is similar to the epiphysis of other long bones, and subject to the same pathology that may occur in similar structures. It may be invaded from the middle ear or mastoid antrum by continuity of tissue or by vascular transmission, also from pathological conditions extraneous to the temporal bone. It is one of a localized purulent lesion, or one of osteomyelitis. Clinical evidence of abducens paralysis, facial or retrobulbar pain in the presence of middle ear or mastoid disease is indicative of petrosal tip pathology. The rationale of the proper surgical treatment depends upon a knowledge of such pathology.

The following is a summary of the gross observations relative to the cellular character and anatomical location of one hundred temporal bones sectioned in various planes. The terms anterior inferior and posterior are used in relation to the three surfaces of the pyramid. The mixed type is placed under the caption that represents the predominant type of cell present. From these observations referable to the surgical anatomy with its clinical and surgical application, the following conclusions are presented:

1. From the observations presented, the cellular character of a majority of temporal bones is the mixed type.

2. The petrosal tip however is predominantly diploetic.

3. The diplo-pneumatic cell type was found to be the most prevalent in the mixed cell type.

4. The cellular character of the mastoid is not a true index to other portions of the temporal bone.

5. The surgical anatomy as presented leads to the inference that the most prevalent route of invasion

to the petrosal tip is from the mastoid by way of the posterior aspect of the pyramid, then by way of the anterior surface from the zygoma, or the peritubal or carotid canal directly from the middle ear and finally by way of the retro-facial area via the bulb cells.

6. Petrosal tip pathology may occur by way of continuity of tissue or by vascular extension from infections in the middle ear or mastoid, also from pathology extraneous to the temporal bone.

7. The peritubal cells serve as a route of evacuation rather than one of invasion to the tip.

8. The logical approach for drainage to localized purulent pathological conditions in the tip is by way of the peritubal cells, and for osteomyelitis a subdural approach either from the mastoid or directly by way of the middle fossa.

9. The variance in the surgical anatomy of the temporal bone impresses one with the fact that clinical evidence, based upon the pathology present, should be the guide to type of therapy used.

SUMMARY OF FINDINGS OF 100 SPECIMENS

RECENT DEVELOPMENTS IN THE DIAGNOSIS OF MENINGITIS¹

SAMUEL J. KOPETZKY M.D., New York, New York
 Professor of Otolaryngology, New York Polytechnic Medical School and Hospital

BEFORE one enters into a discussion of the recent developments in the diagnosis of meningitis, it is necessary to clarify some misunderstandings concerning old concepts. There are many problems concerned in otogenic meningitis. It has been customary to limit our view to the finding of a specific invading organism in the cerebrospinal fluid, to the clinical manifestations which the tissue reactions produce in the form of symptomatology and to autopsy findings.

The desirability of very early diagnosis has been stressed and yet the evolution of the meningeal lesion has not been accorded its grave significance in the earlier stages of its development. The fact has been overlooked that the evolution of the meningeal lesion may be halted before data which are usually accepted as of diagnostic import are available. Finally we have performed anatomical channels of the middle and the inner ear spaces and have accepted them as the obvious tracts along which an infection must travel on its way to the meninges without in many cases having established beyond any reasonable doubt that the endocranial invasion was spread by these routes and we have accepted recorded cases as otogenic without histopathological proof of such invasion. On the other hand, the general principle of infection by retrograde thrombosis and by metastases along blood channels has escaped our serious consideration.

Nor have we studied the cases which have recovered from meningitis in sufficient detail and accorded them the notation which the data they present merits. We have not a general knowledge of those aspects of the clinical picture which drop out in the records of our recoveries. We have been too prone to question the diagnosis in recovered cases. Nor have we always accepted a diagnosis of meningitis unless it gave undoubted evidence of bacterial content in the spinal fluid. We believed that the lesion was of different nature with the differing bacterial content and while it is true that we studied cytology we held that the finding of one class of cells as against another type of cell content in the fluid indicated a different meningeal lesion. We were wont to consider the lesion as an inflammation of the meninges due to a bacterial invader and we left out of account what happened to the brain substance itself and the rôle that this played in the evolution of the clinical picture. We have studied the cerebrospinal fluid and it was held that it was infected, as indeed it was, but we failed to comprehend that much that was found in the fluid was really the washed off products of disease located in the brain tissue and in the blood channels.

Hence, the progress which has marked most of the otological research has been inadequate in this field

of work. Very little progress has been made and today meningitis is still the unsolved problem in our field of medicine.

Before advance can be made it will be necessary to restate fundamentals and postulate upon these a newer conception of this lesion and with this in view I present the following for consideration.

A. The meningeal inflammation including the inflammatory reactions of the brain tissue is the result of bacterial infection which most often reaches the affected parts by the route of the blood stream, traveling either directly by way of the perivascular spaces or, because of a spread endocranially, by a regression thrombosis from the veins of the mastoid process, the petrosal pyramid or the perivascular channels in the labyrinth which latter structures must have been involved in the infection beforehand.

B. Preformed anatomical structures may also be the tract used by an invasion to reach the meninges but in each case, before such shall be accepted as the route involved, histopathological proof must be acquired.

C. Meningitis is a generic term which has the sanction of usage. It is to be understood as describing a lesion which exhibits inflammatory reactions to bacterial invasions involving the meninges, the brain substance and the choroid plexus.

D. Cases of otogenic meningitis differ in patients of differing ages. A perusal of the literature shows that the lesion is more apt to resolve among the young than when it occurs among older individuals. There are more recorded recoveries among children than among adults, and in these the meningitis is apt to develop without the intervention of a purulent mastoiditis.

E. Clinical evidence stresses the fact that the symptomatology is grossly divisible into two groups of symptoms (1) those due to increased intracranial pressure and (2) those due to toxicity including the terminal sepsis from bacterial activity. If the predominating symptoms are those of pressure, this must be relieved early, but cure will not result until the other factors listed are also mastered. Time is gained, however, if the pressure element is relieved, to carry on measures to combat the other factors.

F. The establishment of surgical drainage does not answer the problem presented by meningitis because the lesion is a multiple one consisting of many small foci of active infection spread along the routes of many pial vessels. The problem is concerned with keeping the brain tissue alive. To accomplish this the results of brain tissue cell activity must be removed from the region about the brain cells and the desired means of doing this is

found in keeping the cerebrospinal fluid circulating. Any procedure which stops the circulation of the cerebrospinal fluid defeats the objective which is in view.

G Meningitis, as it is clinically seen, presents itself in stages. Diagnostic data will vary according to the stage at which we first recognize the disease. Each of these stages is in itself somewhat of an entity which changes as the lesion evolves and the clinical picture and laboratory data vary as these changes occur.

H Finally we should recognize that meningitis of otitic origin is as often a complication of acute purulent otitis media as it is the sequel of mastoiditis. We should differentiate those cases occurring during the course of an acute otitic infection from those following an acute mastoiditis. The time intervening between the mastoidal involvement and the first meningeal sign seems to have significance and the record of cases shows that the very poorest results are found in those in which mastoidectomy was necessary during the first week of middle ear infection. The cases which occur as sequelae of middle ear chronicities are again to be comprehended as of different origin. Often they are the result of secondary infections of cholesteatoma or the result of spreads endocranially of unrelieved, often unrecognized, labyrinthine perilabyrinthitis or petrosal pyramid infections. It becomes necessary to differentiate primary meningeal invasions from those which follow infections which are secondary to otitic invasion.

I The healed cases which are recorded in the literature give evidence that cures are obtainable in cases where the clinical picture is not stormy and the symptom complex can best be characterized as weak, and where pressure signs predominate over the signs of toxicity—the Babinski is often absent or only very weakly present and signs of pyramidal tract involvement are not distinctly marked.

The findings in the cerebrospinal fluid give the best indicator of the type of lesion present. The fluid shows the state of being of the brain tissue cells. It is a means of knowing and estimating the amount of intracranial pressure and through the study of its chemistry a knowledge is won of the tissue reactions, the intensity of their activity and the type of bacterial invasion which the given case presents.

Its physical characteristics are deceptive. Clear fluid has been known to show bacterial content and a markedly turbid fluid has been shown to be bacteria free. In view of the importance of the findings obtained from the examination of cerebrospinal fluid, it is necessary to stress the fact that the fluid must be examined immediately after it is withdrawn. The same fluid examined again and again after intervening hours will give different findings.

This holds true for cytology as well as for the chemistry of the fluid. The anti-bacterial properties inherent to cerebrospinal fluid must be remembered and even the search for bacterial contents must be undertaken immediately after the fluid is obtained.

After an interval of time, particularly in the early stages of the lesion, the fluid may be found sterile, whereas, had the examination been made at once, after lumbar puncture, it might have shown bacteria present.

According to most investigators the cerebrospinal fluid is a dialysate. It filtrates from the capillaries of the choroid plexus and from the capillaries of the perineural and penvascular spaces of the central nervous system. Eventually it reaches the venous blood channels, being absorbed into the lateral and longitudinal sinuses of the skull. In the normal state the fluid is in osmotic equilibrium with the blood plasma, and its production and flow may be said to be influenced toward an exaggerated production or a retardation by the relative dilution or concentration of the blood.

Cerebrospinal fluid carries on a dual function. It is concerned with the metabolism of brain cells carrying away the effects of metabolism and its other function is that of equalizing and maintaining intracranial pressure. Meningeal infection disturbs these normal functions. When the fluid cannot carry away the effects of metabolism, when it stands in its circulation results, the cells are poisoned by the products of their own activity and there develop those clinical signs of toxicity and neural reactions which are noted in the clinical picture.

The index of this toxicity can be estimated by studying the choline content of the fluid. Ordinarily the fluid transudes through the capillaries of the choroid plexus in the face of intracranial pressure, and this same pressure influences its absorption. The first effect of a bacterial invasion of the meninges is a great outpouring of fluid from capillary vessels. This is to be comprehended as a defense mechanism—an effort on the part of the body to cleanse itself of the invading pathogenic bacteria and the resultant tissue reactions. Clinically at this stage there is a demonstrable increase in intracranial spinal fluid pressure. To a great extent, the interconnecting orifices between the various ventricles and the meshes of the pia are still open and a real exudate has not yet formed.

The general effect of this increased intracranial pressure is compression of the blood vessels. Both afferent and efferent vessels are involved and there results a lessened oxygenation of the parts and the formation of large quantities of lactic acid follows.

Lactic acid is also present in increased amounts in the blood plasma, especially during fevers. Since the early stage of meningitis with which we are here dealing is always accompanied by fever it becomes necessary to estimate the amount of lactic acid present in the patient's blood plasma at the same time that the spinal fluid estimation is made. Lactic acid has been found to be very much higher in the cerebrospinal fluid than it is in the blood plasma and it is possible to establish a ratio between the two findings. The lactic acid content of the meningeal spinal fluid is apt to be four times that of the lactic acid content of the blood plasma.

There are several interesting and pertinent phenomena that result from the presence of this acid in increased amounts in the cerebrospinal fluid. These results can be comprehended as tissue reactions in the brain tissue cells and in a further chemical interaction in the chemical elements comprising the spinal fluid.

The second stage in the development of the meningitic lesion deals with intrinsic cell changes in the brain tissue, the cells of the choroid plexus, the perineural and perivascular spaces. Cell function becomes hindered, and as a result the effects of cell metabolism are found in the fluid in the forms of choline in greater amounts than normally. I assume that the detail of the lesion, at the stage in question is an edema of the structures concerned. My assumption is based on the known fact that the presence of the lactic acid in increased amounts must result in a changed iso-electric reaction of the spinal fluids and the cells bathed by it. Attention may here be called to the theory of Fisher, who places, in his studies of edema, its causative factor in the water binding property of tissue colloids. When small amounts of acids are added to iso-electric gelatin, its swelling power is enhanced. Fisher contends that the cause of edema is to be found in the accumulation of acid products in the tissues. I realize that Fisher's theory has been critically questioned and is held as not proved nevertheless, as far as the stage of meningitis is concerned with which I am dealing here, his theory seems to find a degree of substantiation. We have brain tissue colloids bathed in a fluid whose reactions are tending to swing toward the direction of 'lessened alkalinity' and as a result we see edema and an interference with cell function.

The presence of the strong lactic acid results in a decrease in the alkaline reserve, or since in the modern nomenclature the actual expression of acidity is termed in common usage the minus logarithm of

the actual concentration of the hydrogen ion which is present, we find a lowered hydrogen-ion concentration. Our finding in meningitic fluids is 6.9 and 7.0 instead of the normal 7.5. When it is remembered that a change of 1 in hydrogen ion is equivalent to ten times that amount in actual change in concentration of hydrogen-ion and that a lowering of the hydrogen-ion of 0.5 in blood cannot sustain life, the actual significance and fundamental character of the lowering of the hydrogen-ion of even 0.5 becomes apparent. The chemical phenomena of increased lactic acid in the spinal fluid has further consequences. The lactic acid being a strong acid drives off carbon dioxide from the carbonates hence in meningitis we should expect to find—and there is in fact found—in addition to the very considerably lowered hydrogen-ion a decreased bicarbonate content.

Summarizing the recent developments in the early diagnosis of meningitis are to be found in the differentiation of the cases. In the recognition that a positive bacterial content is not necessary to a diagnosis of meningitis in the early examination of the fluid after it is withdrawn this examination to include, beside the cytology and the bacterial examination, a chemical examination of the fluid which should show the choline content and the presence or absence of the copper reducing substance¹ the lactic acid in relation to its presence in the blood plasma, the sodium chloride the carbon dioxide and the determination of the hydrogen-ion, all in relation to the same elements in the blood plasma. When we have become habituated to the use of these laboratory aids, we shall have made a distinct step in the early diagnosis of meningeal infections.

In previous papers I called attention to the copper reducing element present in normal spinal fluid and to the significance of its gradual disappearance from the fluid as the meningitic lesion develops and bacteria become evident in the circulating fluid. Its reappearance in the examinations made later as of good prognostic significance.

MENINGITIS—THE RESULT OF DISEASE OF THE PETROUS APEX AND SPHENOIDAL BASIS¹

WELLS P. EAGLETON M.D. F.A.C.S., NEWARK, NEW JERSEY

THE theory of the specificity of function of a tissue, depending upon the embryonic anlage from which its cells evolve, is of surgical value in an understanding of pyogenic lesions of the skull as it furnishes an explanation for the variations in tissue reactions to infection of bones of unlike embryonic origin. Thus a pyogenic inflammation of a petrous apex or the sphenoidal basis (a) runs a distinctive course and (b) requires a different surgical viewpoint than infections of an adjacent cranial bone, such as mastoiditis, nasal sinusitis, or osteomyelitis of the cranial vault.

Petro-apicitis is frequently an unrecognized cause of meningitis. In the vast majority of cases, it is a true osteomyelitis. Petro-apicitis represents a different pathological and surgical entity from the recognized forms of mastoiditis, with which apical suppuration is usually but not invariably associated, occurring as it does in a genetically different type of bone.

Infections within a petrous apex have a much greater tendency to spontaneous cure, i.e. without the opening of the infected area, than has the associated mastoid suppuration, because in apical suppuration the infection is influenced by the presence of red bone marrow.

Clinical classification of infections of the petrous apex and sphenoidal basis. I propose a clinical classification, based on my experience with 42 cases of petro-apicitis and 24 cases of infection of the sphenoidal basis, as follows: (1) reactive and reparative osteitis; (2) non-suppurative congestive cases—symptoms due to venous stasis; (3) chronic bone sepsis cases (without macroscopical pus); (4) abscess of apex—(a) without a tract, (b) with a tract; (5) acute septicaemic cases, associated with a continuous positive blood culture and meningitis.

Intrameatal type of facial paralysis. There occurs a specific type of facial paralysis in petro-apicitis which is seen in no other process. This "suppuration of a facial" (an intrameatal type of facial paresis) is transient in duration and limited in extent. It is characterized by the partial non-closure of the lower lid during sleep, although the ability spontaneously to close the lid completely is not lost.

Meningitis from suppuration of the apex is at first limited to the cisterns (a) covering the floor of the middle fossa, or (b) mesial to the internal auditory meatus of the posterior fossa.

Infection of the sphenoidal basis. The pattern of blood supply within the red bone marrow accounts for the unique reparative and specific protective properties of the sphenoidal basis, also possessed, but to a lesser extent, by the petrous apices. It also explains the rarity of small sequestra in pyogenic lesions of an apex or of the sphenoidal basis.

A symptomless infection of the sphenoidal basis is a frequent, but generally overlooked, cause of meningitis, especially of the pneumococcal type. In pneumococcus Type II meningitis, I have cured cases by simply draining the sphenoidal sinus and by the administration of serum.

Control of infection by metaplastic reconversion from yellow (acellular) fat marrow into red (cellular) bone marrow. During infancy and childhood, all the bones of the torso and extremities are filled with red cellular bone marrow containing no fat. However none of the cranial bones, with the exception of the sphenoid, the occipital and the two petrous apices (which form the primordial basis of the skull) contain red bone marrow, although the bones of the tympano-antral area of the nasal accessory cavities which increase in size by pneumatization are, at birth, filled with yellow fat marrow. The red (cellular) marrow at osseous maturity subsequently is converted into yellow acellular fat. This metamorphosis from red into yellow fat marrow occurs in all red marrow containing bones, with the exception of the sphenoid, the segmental portion of the occipital, the vertebrae, the ribs, and the os innominatum, whose spongy tissue has a preponderance of red cellular bone marrow throughout life.

However if at any time an irritant, notably infection or cancer enters, or even indirectly affects a marrow containing bone, its yellow (acellular) fat marrow may become reconverted into red (cellular) marrow. This rapid metaplastic reconversion from yellow (acellular) fat marrow to its original state of red (cellular) bone marrow is, I believe, an evidence of the tissue mechanism which red marrow containing bones possess for the local control of infection.

Metaplastic reconversion from pneumatic air filled spaces into the original bone marrow state within an apex accounts for the infrequency of apical abscess. Primarily the petrous apex is a red (cellular) marrow containing bone, its red marrow being converted into fat or replaced by air filled cells early in life. It does not combat infection simply by pouring forth round polymorphonuclear cells brought to it by the circulation, as is the reaction of the mastoid to suppuration, but on the approach of infection the pneumatic spaces within the apex may return to their original bone marrow state. Thus it may become the seat of a unique physiological metamorphosis, to which attention has not been previously directed. This phenomenon I have observed in at least 2 cases, as demonstrated at postmortem examination.

Treatment of meningitis from apical or sphenoidal infection. If we are to be successful in the treatment of meningitis, we must abandon many of our pre-conceptions, for in the past all surgical treatment has been based too much on the principle of drain-

age of the entire arachnoid circulation, which is impossible.

In my opinion, operation on the meninges, if preceded by ligation of the common carotid artery gives a higher percentage of recoveries than other wise, because carotid ligation relieves venous congestion, which postmortem examinations show to be invariably present in all cases of meningitis.

In the surgical treatment of meningitis it is of paramount importance that the surgeon should early

diagnose and thoroughly drain the primary focus of infection in the petrous apex or in the sphenoid—lesions that are curable for eradication of a primary focus in a bone, associated with the evacuation of an adjacent localized collection of infected cerebrospinal fluid, allows the protective and reparative mechanism of the meninges an opportunity to act. This procedure has been followed by a larger percentage of recoveries than any other method of treatment, either surgical or medicinal.

NON-OPERATIVE TREATMENT OF NASAL SINUS DISEASE¹

WILLIAM MITHOEFER M.D., F.A.C.S. CINCINNATI, OHIO

THE treatment of chronic nasal sinus disease in a non-operative manner is, in the majority of instances, an unsatisfactory procedure. We must, therefore when attempting this method of treatment select our cases with discretion and not continue to treat for any length of time a patient who is in need of a more radical procedure. We shall eliminate immediately from our discussion the treatment of all very acute inflammatory processes of the nose and nasal accessory sinuses whether associated with fever or not. We believe that any local treatment at this time unless it be the application of a vasoconstrictive agent will only kindle the fire and be the cause of a reaction and a spread of the disease.

The chief consideration will, therefore be the subacute and chronic infections. How shall these patients be treated non-surgically? In the first place let it be said that no one fixed plan of treatment can be used in all cases. The various means and methods of treatment which we have employed in our practice are the following: systemic treatment of the nasal mucosa, median rhinoscopy, treatment of nasal recesses, tampons suction with irrigation, dilatation of the ostia and nasofrontal duct, irrigation of the sinuses, and infra red and ultraviolet therapy.

We may rightly say that the most difficult problem before the medical profession today is the study of the constitution of the patient, inasmuch as each individual reacts to certain irritants according to the character of his inner qualities, and these qualities we term constitution. It is our belief that the treatment of the constitution of the patient with diet, hygienic measures of living, endocrine and intestinal therapy, and the examination of the blood for various changes is of greater importance than the detection of the type and virulence of the bacteria. To emphasize the bacterial aspect only and give vaccines specific or non-specific, is not sufficient. We must not forget that the bacteria would probably not have been present if the constitutional elements of the patient had not been ready to receive them.

A patient in whom the constitutional elements are inadequate to combat infection readily acquires a chronic state of the nasal sinus mucosa following an acute infection. In these patients, two physiological functions are easily lost, namely movement of the ciliated epithelium, and secretion of mucus—both very important functions when infection takes place. A patient whose tissues are unable to perform their physiological function at the time of an infection is left with an oedematous nasal mucous membrane which may cause retention in the recesses—a favorable condition for the establishment of chronicity.

An acutely inflamed maxillary sinus should rarely if ever be irrigated in the presence of fever, because of the danger of causing a systemic infection following the lavage. Patients are usually able to combat the infection in an antrum, provided no other irritant appears upon the scene such as the irritation which may be caused by an antrum lavage. As soon as another insult is added to the infection already present in the antrum an imbalance of the body mechanism takes place. The bacteria gain the upper hand and many times, because of the injury to the mucous membrane from puncture a secondary inflammation ensues and a local or general sepsis may be the result.

In applying the various forms of treatment, both local and general, we must forget for the time being at least, that we are rhinologists limited to a small specialized field. We must try to be real doctors who are making a special study of a very sensitive part of the body—the nose and its adnexa—areas which are affected very readily by a systemic dyscrasia.

A hasty surgical approach is, in our opinion, a great mistake. Surgery in most instances, should be undertaken only after a careful analysis has been made or should follow the conservative treatment after this has proved of no avail. When surgery is necessary its success will depend on the ability of the surgeon to detect every affected sinus, and his accuracy in removing all of the diseased mucous membrane.

THE OPERATIVE TREATMENT OF NASAL SINUS DISEASE¹

EDWARD C. SEWALL, M.D. SAN FRANCISCO, CALIFORNIA

A DISCUSSION of the operative treatment of nasal sinus disease necessitates correlating various technical endeavors, some as yet unpublished and evaluating methods and hoped-for improvements in treatment with which I have been continuously occupied since the publication of my original article entitled "Fronto-Ethmo-Sphenoid Operation under Local Anesthesia," in the *Archives of Otolaryngology* in 1926. I am inclined to quote as follows from that article because what was said then needs even more emphasis today.

Indications for operation. The operative treatment of sinus disease is a subject that I feel should be approached with considerable caution. I am proposing a rather radical line of procedure that I feel may add to our efficiency in handling certain cases. Still I do not wish to leave the impression that I am applying these measures except after careful study or when former unsuccessful operative work would seem to make their applicability advisable. I have gone into the question of diagnosis frankly but must make the point plain that the diagnosis arrived at does not condemn the patient to operative measures. It becomes a matter of the nicest judgment on the part of a well trained surgeon, probably with the invaluable assistance of the internist, to determine whether the sinuses should be operated on. A rubric of the operative indications would only be about as useful as those that have been compiled to tell us when to operate on a chronic running ear. Many people with apparently excellent health are sufferers from infected sinuses. The hacking and spitting that is so commonly heard, and the mucopurulent expectoration seen on our city pavements, are evidence of the widespread distribution of sinus disease. While admitting that many people seemingly well are carriers of this infection, it is obvious that they are apparently in good health in spite of the sinuses. It is a menace constantly carried about, and often proves to be the vulnerable heel of Achilles, leading to the establishment of some important vital disorder. The inability to discover the true focus, the removal of a wrong focus or the incomplete treatment of the right focus have brought a certain amount of approbrium on the focal infection theory. Incomplete treatment of the right focus is practiced so commonly in connection with sinus disease, that the specialists must take the onus of the lack of understanding of the importance of sinus infection on the part of many of the medical profession. These men have conscientiously and repeatedly referred patients for elimination of nasal infection. Failure after nasal sinus operation to cure the disorder in which the internist was interested, very frequently has been interpreted as indicating improper diagnosis. The use of the method I have advocated of gathering the nasal and post-nasal discharges from the patient on pieces of cloth will show the internist himself whether the results he has asked for have been achieved.

Ordinarily before operation on the sinuses is to be considered, all other factors that may be contributing to the trouble should be corrected, climate has been given especial prominence. Whatever therapeutic measures have been found useful may be employed.

Constructive surgery when indicated, including submucous resection, tonsillectomy, and adenoidectomy should be given precedence and followed by sufficient time for accomplishment of results before the destructive surgery of the sinuses is advocated.

In presenting my present operative plan, it may be said that the intricate technical developments have followed naturally upon the introduction of a bloodless technique. This was accomplished by ligation of the vessels supplying the operative field, under local anesthesia secured largely by blocking the nerves before or at their entrance into the field.

Sinus surgery may well be divided into a pre- and a post ligation period. Prior to the introduction of these methods, general anesthesia was commonly used in external sinus technique.

The literature contains many descriptions of the bloody operative field where all nicety of technique was impossible.

The operative steps may be briefly summarized as follows:

1. The patient lies on the back, semiconscious from the effects of sodium amytal, scopolamine and morphine.

2. Cocaine is applied topically in the nose.

3. Novocain is injected deep into the orbit to block the nasal branches of the fifth nerve supplying the operative field.

4. A small incision at the inner angle of the orbit suffices, and leaves practically no scar.

5. The frontal sinus and the ethmoids are entered through a window cut through the frontal and maxillary bones.

6. The ethmoid vessels are ligated in the orbit.

7. The frontal and ethmoid sinuses are thoroughly inspected and cleared of disease.

8. The sphenopalatine artery is tied, permitting the intricate sphenoid technique.

9. A posterior submucous resection allows the removal of the whole of the floors of both sphenoids.

10. Flaps prepared from nasal mucosa are used to line the operative fields and prevent the closure of the nasofrontal drainage opening.

11. The wound is closed at once with metal clips, no packing, no bandage whatever.

CANCER OF THE LARYNX, INTRINSIC, ITS SURGICAL CURE¹

GABRIEL TUCKER, M.D., PHILADELPHIA, PENNSYLVANIA

THE clinical incidence of cancer of the larynx is apparently much greater than the incidence indicated by the rate of deaths from laryngeal cancer. The rate of laryngeal cancer deaths is given as 0.8 per cent, deaths from cancer of the esophagus 1.5 per cent, and deaths from cancer of the lung as 2.1 per cent of all cancer deaths. In a bronchoscopic practice, where the work is limited to the diagnosis and treatment of diseases of the larynx, esophagus, and lungs there were seen during the same period 200 cases of cancer of the larynx, 250 cases of cancer of the esophagus and 57 cases of cancer of the lung. With the present perfection of methods of early diagnosis, resulting in the surgical cure of at least 80 per cent of the early cases, the percentage of deaths from cancer of the larynx can no longer be taken as the true rate of incidence of laryngeal cancer.

Symptoms. In the consecutive series above noted of 200 cases of laryngeal cancer (1) it was found that every patient manifested either *chronic hoarseness* or *local discomfort* or both *chronic hoarseness* and *local discomfort* early in the course of the disease. In this study there were 144 cases (72 per cent) which were apparently of intrinsic origin. Chronic hoarseness was an early symptom in every case, but in many cases when the patients were first seen the lesions were far advanced and presented one or more of the signs and symptoms of inoperable cancer, namely dyspnea, dysphagia, aphonia, adenopathy. If the symptoms of chronic hoarseness and local discomfort were properly evaluated and routine diagnostic studies done in every case, cancer of the larynx would be found while the lesion was still early and curable by surgery.

Diagnosis. Cancer of the larynx appears as a definite local lesion and when far advanced, has a characteristic appearance. In its beginning the appearance of the lesion is rarely characteristic, and in fact the lesion may not be cancer. Clinically we must recognize that there is a precancerous lesion in many cases. To the trained eye of the expert laryngologist the typical lesion may be recognized as cancer from the appearance alone. However, we are not justified in waiting until this characteristic appearance develops to make a diagnosis of laryngeal cancer. Even when the appearance is definitely characteristic, a final diagnosis should not be made until after a thorough routine examination, serological study and X-ray examination of the neck and chest, have been done, and the finding of cancer has been confirmed by biopsy. As an example of the inadequacy of diagnosis without biopsy may be cited the case of a laryngeal cancer typical in appearance which on biopsy showed both cancer and tuberculosis (2).

Biopsy. The removal of tissue for histological examination by direct laryngoscopy has reached a

state of perfected technique that makes the procedure harmless if it is properly done. The reason we have not been able to cure more cases of cancer of the larynx by surgery in the past lay not with us but with those general practitioners and otolaryngologists who were afraid of biopsy and refused to have tissue removed until the appearance was characteristic, and the lesion hopelessly late. Biopsy of a non-cancerous growth in the larynx will not cause it to become cancer. Neither will biopsy propagate cancer in the larynx where it already exists if the proper course is followed. With the present technique a histological diagnosis based on a fixed specimen of tissue may be obtained within 48 hours, and surgical treatment can be promptly carried out. The lymphatic drainage within the larynx is such that there is no probability of metastatic extension within this short period.

Treatment. "Early diagnosis is the pearl without price in the surgical cure of cancer of the larynx." (3) Laryngofissure and total laryngectomy are the surgical procedures of choice in the treatment of cancer of the larynx.

Laryngofissure. Cancer within the larynx, intrinsic, is the most favorable type for surgical treatment. If the cancer involves the anterior two-thirds of the vocal cord—the most frequent site of origin—and has not extended beyond this, laryngofissure will cure over 85 per cent of the cases. If the growth involves the anterior commissure and both cords in the anterior portions, laryngofissure by a special technique for anterior commissure growths will result in cure in an equally high percentage of cases. Laryngofissure saves the patient's larynx as well as his life. A subperichondrial resection of the diseased area with a wide margin of normal tissue surrounding it is all that is required in properly selected cases of laryngeal cancer because the peculiar lymphatic drainage in the anterior portion of the larynx prevents rapid extension of the disease. The cartilage is not removed unless it is involved. The procedure can be carried out under local anesthesia and there should be no operative mortality. Following laryngofissure the larynx must be kept under close observation for at least a year. If granulations appear at the site of excision of the growth they should be removed by direct laryngoscopy and submitted to histological examination. If there should be recurrence of the cancer—the rate of recurrence is less than 15 per cent—laryngectomy can still be performed with a probable cure of 90 per cent of the recurrences.

Laryngectomy. Total laryngectomy should be done when there is more extensive involvement. Where the disease originates in the posterior portion of the larynx, or extends subglottic, or involves the ventricular bands or the base of the epiglottis, total

¹Abstract of paper presented before the Section on Otolaryngology, Clinical Congress of the American College of Surgeons, Boston, October 9, 1914.

laryngectomy is required. In cases in which the under surface of the epiglottis only is involved, the epiglottis can be removed completely by a laryngofissure approach; the remainder of the larynx being preserved.

The surgical procedure selected for the individual case depends on two factors: (1) the location and extent of the lesion, (2) the grading of the cancer cells in the growth.

The location and extent of the lesion is determined by careful mirror examination, by X-ray examination of the neck and chest, including the larynx and esophagus, and by direct inspection of the larynx, pyriform sinuses and upper esophagus before operation. After the larynx is opened the lesion also is carefully examined.

Cell grading is of greatest importance in determining the radiosensitiveness of the cancer; post-operative irradiation may be of great value in radio-sensitive types of cancer. Pre-operative irradiation is regarded as inadvisable by most laryngeal surgeons.

SUMMARY

1. The incidence of cancer of the larynx seems to be relatively greater than the rate of cancer deaths indicates. Because of the early diagnosis and the surgical cure of a large number of cases, the death

rate cannot be taken as a true indication of the incidence of laryngeal cancer.

2. Chronic hoarseness and local discomfort are always early symptoms in cancer of the larynx.

3. Biopsy by direct laryngoscopy, should be the final diagnostic step in cancer of the larynx. Biopsy will not produce cancer; and where cancer exists and biopsy is done. If the proper routine is followed, surgical removal of the cancer can be carried out before metastasis can occur.

4. Surgical treatment, laryngofissure and laryngectomy will cure practically all cases of intrinsic cancer of the larynx. Laryngofissure in properly selected cases will save the larynx as well as the patient's life. Educating the laity and the general practitioner to recognize that local discomfort and chronic hoarseness may mean cancer is the best most important step in the cure of cancer of the larynx.

PATHWAYS OF APPROACH TO THE PETROUS PYRAMID¹

MARVIN F. JONES, M.D. New York, New York

IN studying surgical methods for the relief of petrositis, it becomes necessary to focus attention on the intimate anatomical structure of the temporal bone. Pneumatized tracts are of major importance.

More attention has been attracted to the acute phases, while the chronic stages with acute exacerbations are less widely recognized.

All operative procedures (with one exception) aim at the superior group of cells, while the logical method of drainage would seem to be through dependent portions of the bone.

The symptomatology developed recently would seem to indicate the extent and location of pathological changes, thus facilitating an intelligent choice of surgical procedures.

Impaired hearing and labyrinthine symptoms plus location of pain are proposed as indicative symptoms.

A discussion of the surgical procedures already advocated, and the difficulties found by personal experience illustrate some of the pitfalls.

Histological sections, X-ray pictures, and gross dissections illustrate the statements embodied in the paper.

Abstract of paper presented before the Section on Otolaryngology, Clinical Congress of the American College of Surgeons, Boston, October 4, 1934.

COMMITTEE AND DEPARTMENT REPORTS

DEPARTMENT OF CLINICAL RESEARCH—ALBERT J OCHSNER MEMORIAL

BOWMAN C. CROWELL, M D CHICAGO ILLINOIS
Associate Director American College of Surgeons, Director of Clinical Research

THE work in clinical research which is being conducted by the College includes that of the following committees

Committee on the Treatment of Malignant Diseases
Committee on the Archives of Malignant Diseases

Committee on Bone Sarcoma
Committee on Clinical Laboratories
Committee on Fractures

A survey of the work of this department which has been performed during the past year is embraced in the reports of the individual committees

COMMITTEE ON THE TREATMENT OF MALIGNANT DISEASES

CHARLES A. DUKES, M D OAKLAND CALIFORNIA, Chairman

THIS Committee, founded in 1922 has made a consistent study of records and clinics with the hearty co-operation of the surgeons pathologists and radiologists, throughout the United States and Canada.

Standard uniform record forms have been designed by the Committee, which have been used widely and adopted by cancer clinics, and hospitals where cancer clinics have not yet been formed. In 1930 the standard for organization and conduct of cancer clinics was formulated by the Committee and adopted by the Board of Regents. The wide acceptance of this standard of hospitals in the United States and Canada has been a pleasing result of the College activity and the figures indicating the growth of the movement will be presented at this meeting by the Director of Clinical Research.

The report of this Committee would not be complete without an acknowledgment of appreciation for the work of Dr Robert B. Greenough, who has been Chairman from the beginning until this year. The amount of time which he has spent and the skill which he has shown in completing the organization and in working through the mass of reports and forms which have been necessary to the completion

of this program I am sure will be appreciated by everyone, and there is considerable fear on my part that I shall be unable to live up to the high standards which his leadership has created.

It is also fitting that we should pay tribute to that great physician and surgeon who devoted so much of his life to this work—Dr Burton J. Lee, whose passing to the Great Beyond occurred shortly after the 1933 meeting.

The personnel of the Committee on the Treatment of Malignant Diseases is as follows:

Charles A. Dukes, Oakland, Chairman
Bowman C. Crowell, Chicago, Secretary
Frank E. Adair, New York
A. C. Broders, Rochester, Minn.
Curtis F. Burnam, Baltimore
George Crile, Cleveland
Edwin C. Ernst, St. Louis
Rupert H. Fike, Atlanta
John M. T. Finney, Baltimore
Robert B. Greenough, Boston
Frank W. Lynch, San Francisco
Alton Ochsner, New Orleans
Eugene P. Pendergrass, Philadelphia
George Gray Ward, New York
Francis C. Wood, New York

STANDARDIZATION OF CLINICAL LABORATORIES

AT the meeting of the Committee on the Standardization of Clinical Laboratories, held in October 1936 the following Minimum Standard for Laboratories was adopted and has been approved by the Board of Regents:

1. That the clinical laboratory shall be under the direction of a graduate in medicine, especially trained in clinical pathology.
2. That the clinical laboratory shall be prepared to perform satisfactory work in (a) histopathology (b) bacteriology and parasitology (c) serology (d) hematology and (e) chemical and morphologic examinations of other body fluids, exudates, transudates, and excreta.
3. That all tissues removed at operation shall be

examined in the laboratory and reports rendered thereon.

4. That an easily available copy of all reports shall be filed in the laboratory and one with the patient's record. In histopathology there shall be in the laboratory a cross index of at least the name of the patient, of the hospital or laboratory number of the patient, and of the lesion or organ. There shall be preserved also for at least 3 years, either section, embedded tissue or gross tissue from each case from which tissue is removed.

5. That a uniform system of charges for laboratory work shall be enforced.

6. That the clinical pathologist shall attend the monthly staff conferences of the hospital.

CANCER CLINICS APPROVED TO OCTOBER 1, 1934

IN 1930 the Board of Regents of the American College of Surgeons, on the advice of its Committee on the Treatment of Malignant Diseases, announced its policy of emphasizing the necessity of making the benefits of contemporaneous knowledge of cancer available to each and every cancer patient in the country. Already existing hospitals were recognized as the natural centers in which modern diagnostic and therapeutic procedure should be conducted, and a minimum standard was formulated for cancer clinics in such hospitals.

Information concerning the cancer clinic movement of the College was published, and all approved hospitals of one hundred or more beds were urged seriously to consider cancer clinic organization. Representatives of the College have visited the hospitals, have consulted with members of their medical staffs and administrators, and have furnished to the College a summary of the activities of each hospital with regard to the diagnosis and treatment of cancer. Ordinarily these hospitals have the personnel and equipment for such service, but we believe that a definite organization for this special service is of advantage in obtaining the maximum of efficiency in the campaign against cancer.

The College announces its second list of the hospitals conducting cancer clinics which conform to its minimum standard. The conduct of such clinics varies somewhat according to the character of the hospital with regard to whether its patients are charity patients or otherwise. Some institutions have established diagnostic clinics but refer the patients elsewhere with advice as to the nature of treatment that should be administered. In certain other large institutions some departments have organized cancer clinics for the recognition and care of cancer in their patients while other departments have not so organized. Cognizance of these facts is taken in the publication of the list of institutions that

are approved from the standpoint of their cancer clinics.

It is further recognized that certain institutions have accepted the minimum requirements for cancer clinics as formulated by the American College of Surgeons and are endeavoring to carry them out, but for lack of time or other acceptable reasons have not yet been able to do so in every detail. In the following list they are indicated as having "provisional approval."

Total cancer clinics surveyed	239
Approved cancer clinics in general hospitals	97
Provisionally approved cancer clinics in general hospitals	55
Approved cancer diagnostic clinics	23
Hospitals with departments conducting approved cancer clinics	6
Total approved cancer clinics	181

The publication of the list of 181 approved cancer clinics in no way indicates that effective cancer treatment cannot be obtained elsewhere, but serves to show that these institutions have formally organized for this purpose as part of a country wide campaign in behalf of the cancer patient.

In addition to the list of approved cancer clinics the College has information concerning 53 others which for one reason or another are not yet ready for a rating by the College, and still 80 other hospitals have definitely signified their contemplation of the formation of such clinics in the future.

MINIMUM STANDARD FOR CANCER CLINICS IN GENERAL HOSPITALS

1. *Organization.* There shall be a definite organization of the service, and it shall include an executive officer and representatives of all the departments of

the hospital which are concerned in the diagnosis and treatment of cancer. The services of a secretary and of a social service worker shall be available.

2 *Conferences* As an essential feature of the service there shall be regular conferences or consultations at which the diagnosis and treatment of the individual cases are discussed by all members of the clinic who are concerned with the case.

3 *Patients* Reference to the cancer clinic of all patients in whom the diagnosis or treatment of cancer is to be considered shall be either voluntary or obligatory in accordance with the vote of the medical staff or of the governing board of the hospital.

4 *Equipment* In addition to the diagnostic and therapeutic surgical equipment which is required in every approved general hospital there shall be available an apparatus for X ray therapy of an effectiveness which is generally agreed upon as adequate, and an amount of radium sufficient to insure effective treatment.

5 *Records* In addition to the records which are required in every approved general hospital, there shall be additional records of (a) the details of the history and of the examination for cancer in different regions of the body, such as are indicated on the form records which are recommended by the Committee on the Treatment of Malignant Diseases, American College of Surgeons, (b) the details of the treatment by radium or X ray as indicated on the form records which are recommended by the Committee on the Treatment of Malignant Diseases, of the American College of Surgeons, (c) periodic examinations at intervals for a period of at least five years following treatment.

6 *Treatment* The treatment of cancer patients shall be entrusted to the members of the staff of the cancer clinic except in cases in which adequate treatment in accordance with the collective recommendation of the staff of the cancer clinic can be procured otherwise.

REGISTRY OF BONE SARCOMA

BOWMAN C. CROWELL, M.D. CHICAGO, ILLINOIS, Registrar

THERE have been 197 cases submitted to the Registry during the past year. Of these 161 cases have been registered.

Of 537 of the cases which have been circulated during the year opinions have been rendered by 33 doctors.

The total number of cases in the Registry is now 1703 classified as follows:

Osteogenic sarcoma	773
Ewing's sarcoma	171
Myeloma	73
Lymphosarcoma	8
Inflammation	89
Periosteal fibrosarcoma	27
Metastatic tumor	46
Angioma	13
Hemangio-endothelioma	14
Benign giant cell tumor	313
Giant cell tumor malignant	18
Benign osteogenic tumor	58
Unclassified and miscellaneous	70
Not bone tumors	21
Parosteal osteogenic sarcoma	4
Liposarcoma	4
Xanthoma	1
Parosteal Fibrolipoma	2

1703

There are 504 cases of osteogenic sarcoma that were treated 5 years or more ago and 126 cases of Ewing's sarcoma that were treated 5 years or more ago.

In March, 1926, Dr. Ernest Amory Codman, the originator and first Chairman of the Registry of Bone Sarcoma, published 25 criteria for establishing the diagnosis of osteogenic sarcoma and 13 registered cases of 5 year cures analyzed according to these criteria.

From time to time since then the Registrar has announced an increasing number of such "5 year cures" that have been registered. The present report presents 74 cases of osteogenic sarcoma and 10 cases of Ewing's sarcoma that have lived clinically free from the disease for periods of 5 years or more following treatment.

Three of the original 13 cases reported by Dr. Codman died. B. S. R. No. 100 died 11 years after treatment with metastases in the spine, ribs and lungs after having been clinically free of the disease for 10 years or more. B. S. R. No. 30 died of paralysis 24 years and 9 months after treatment. B. S. R. No. 29 died from cancer of the breast 17 years and 5 months after treatment. The other 10 original "cures" are still alive and free from the disease at the time of the latest report.

Five of the other cases here reported have died after the expiration of the 5 year period. B. S. R.

No. 1437 from cardiac and cerebral sclerosis, B. S. R. No. 176 following a prostatectomy. B. S. R. No. 970 with probable pulmonary metastases 8 years after treatment. B. S. R. No. 156 9 years after treatment from heart disease without recurrence of the tumor and B. S. R. No. 1035 from metastases.

At least 3 cases (B. S. R. Nos. 183 and 367) have had definite evidence of metastases which have disappeared after treatment.

Seventy-one of the 74 five year cures of osteogenic sarcoma were treated by surgical methods, and of these 39 had surgical methods only. In the other 35 cases surgery was supplemented by radium or X ray treatment or Coley toxins or some combination of these agents. In 16 of the cases Coley toxins were administered.

The cases in which amputation was not performed are as follows:

B. S. R. No. 668 Local excision of tumor of lower part of femur followed by radium.

B. S. R. No. 183 Local excision of tumor of lower part of tibia followed by radium and Coley toxins.

B. S. R. No. 533 Excision of tumor of ilium followed by radium.

B. S. R. No. 585 Tumor of ilium treated by X rays only.

B. S. R. No. 109 Tumor of rib treated by resection followed by radium.

B. S. R. No. 373 Tumor of rib was explored and then treated by radium and Coley toxins.

B. S. R. No. 759 Tumor of scapula treated by excision and X rays.

B. S. R. No. 867 Tumor of scapula treated by excision alone.

B. S. R. No. 1523 Tumor of humerus treated by excision alone.

It is interesting to note that 20 of the cases had some form of operative procedure on the tumor at periods of 1 day to 5 years prior to amputation. These operative procedures consisted of single or multiple biopsies, curettages, explorations, excisions or resections.

There are in the Registry 504 cases of osteogenic sarcoma that were treated 5 years or more ago. No figures are included in this report to show the percentage of cures for the reason that this series does not represent a consecutive series of cases treated, and moreover there is a tendency for doctors to pay more attention to the registration of their unusually successful cases than to a registration of all of their cases.

EWING'S SARCOMA

Ten of the registered cases of Ewing's sarcoma have lived from 5 to 21 years following treatment. These cases occurred in a group of 126 registered cases of this disease.

All 10 cases were subjected to surgery. In 7 of them amputation was performed. In the other 3 there were excisions. Six of the 7 amputated cases also received Coley toxins and of these, 5 had radiation in one form or another. Four of the 7 amputated cases had one or more surgical procedures at some period prior to the amputation.

The personnel of the Committee is as follows:

Dallas B. Phenister, Chicago, Chairman
Bowman C. Crowell, Chicago, Registrar

Edwin I. Bartlett, San Francisco
Everett L. Bishop, Atlanta
Joseph C. Bloodgood, Baltimore
Barney Brooks, Nashville
Ernest A. Codman, Boston
Charles L. Connor, San Francisco

Henry W. Meyerding, Rochester, Minn.
John J. Morton, Rochester, N. Y.
Channing C. Simmons, Boston

COMMITTEE ON FRACTURES

FREDERIC W. BANCROFT, M.D., New York, New York, Chairman

THE purpose of the Committee on Fractures is to stimulate interest in and improve the treatment of fractures. The Committee functions through three main channels: first, the Annual Meeting of the American College of Surgeons; second, the Annual Meeting of the General Committee on Fractures; third, Regional Groups.

1. At the Annual Meeting of the American College of Surgeons the Committee arranges for the fracture symposium and the fracture oration. It also gives practical demonstrations in recognized methods of fracture treatment and holds a clinical conference with members of the various regional groups.

2. The Committee meets in January of each year. The first day is given over to clinics wherein advances in the treatment of fractures are shown and the second day is devoted to reports of the various sub-committees. The sub-committees are as follows: (a) Scientific—presenting the latest advances in research or treatment; (b) Educational—both under graduate and postgraduate; (c) Regional groups; (d) Physical therapy; (e) Bone plates and screws; (f) American Railway Surgeons; (g) Editorial; (h) Transportation and ambulance equipment.

The Committee has concentrated its efforts during the past year on two main subjects: (1) the immediate application of traction at the site of injury following the dictum "splint them where they lie"; (2) the early reduction and improved treatment after the patient arrives at a hospital.

The application of immediate traction to long bone fractures has been more and more emphasized as high speed locomotion by automobiles and air planes has increased the number of serious injuries along highways. The deformities resulting from improper or no splinting during transportation not only delay the healing time of the fracture but also may cause serious shock, hemorrhage or death. Men experienced in the treatment of fractures are convinced that reduction before edema and swelling occur results in better replacement of fragments and hence diminished time of disability and better function when union has occurred.

Because of a limited time at my disposal, I shall report only on first the activities of the Committee

on Transportation, second, Editorial Committee, third, Regional Groups.

1. *Transportation*. A new edition of the American Red Cross First Aid Text Book is expected to appear within the next year. We have the assurance of their Director of First Aid and Life Saving that this new edition will contain the suggestion that fixed traction transportation be taught to all Red Cross classes, instead of simply to large groups, such as police, fire and industrial departments, as the present edition states. Instruction in this method is being continued actively before groups of approved Red Cross instructors and it is expected that within a year and a half all instructors will have been prepared to teach this method. In 1930 a pamphlet was sent out by the Red Cross to all chapter chairmen outlining a procedure for establishing first aid posts on the highways. On account of the economic depression this work has been held largely in abeyance. As soon as business improves they expect to enter actively into this field again.

The major portion of transportation of the injured in the country as a whole is done by the undertakers. One of their national organizations sent out a questionnaire on this subject prepared by the sub-committee to its entire membership. Replies were received from about 70 per cent. Of these about 70 per cent were in favor of adopting fixed traction for use on their ambulances and said they were ready to do so if they could be trained. The other large national organization of funeral directors is considering adoption of the method through its Committee on Education.

Many police and fire emergency squads have been trained and are using the method as a routine, also some mines and industrial plants which have their own first aid crews.

An important new contact, largely through the efforts of Dr. Thomson of Lincoln, Nebraska, has been made with the National Council of the Boy Scouts of America. Dr. Owen and Dr. Scudder have been of great assistance in this. Mr. Fred C. Mills, National Director of Health and Safety Service, is enthusiastic in his efforts to educate his personnel in fixed traction. At their annual meeting in June

1934 a demonstration of the application of the Thomas splint was given before the heads of their professional staff. About 30 men were present from all parts of the country. At Mendham, New Jersey they maintain national training headquarters for professional scout leaders. They are key men whose duty it is to teach the scout masters throughout the country. At the last two schools demonstration of fixed traction has been given to about 50 men. Mr. Mills personally has given demonstrations to 4 group meetings of scout masters in New York, New Jersey, Ohio and Minnesota.

Before the Boy Scout Camps opened in the summer of 1934 a bulletin was sent from their National Headquarters asking all Scout executives to buy or borrow and place in their camps, a set of Thomas splints. There are about 500 of these camps in the United States. Dr. Thomson has prepared a description of the application of fixed traction illustrated with excellent photographs of Boy Scouts carrying out the procedure. The Boy Scouts is an organization of about 650,000 boys, 300,000 men, and 30,000 training instructors. We believe that this contact is one of the most important we have made in that it will be a constant means of educating the general public to demand of the medical profession proper fracture transportation. The National Organization of the Boy Scouts has agreed to do its utmost to further our campaign.

2. *Editorial committee.* The fracture manual was originally sent out in 15,000 pamphlets and has had since that time two printings in a revised form, 3,000 in the first and 2,000 in the second edition. Of these the greater number were distributed in the United States but in addition they were distributed in 20 countries outside the United States and Canada. The Professor of Surgery in the University of Australia asked for the privilege of incorporating The Outline in a pamphlet which he would issue to the students.

3. *Regional groups.* The regional groups function through clinical meetings in hospitals, executive meetings, and travel trips to various clinics. In Boston the regional group has done a great deal to stimulate education throughout the greater part of New England and to improve the treatment of fractures in the various hospitals in Boston. In New York, through the efforts of the local group the commissioner of hospitals ordered that Thomas splints for leg and Murray Jones splints for arm fractures be made a part of the equipment of every ambulance caring for city patients. Through the efforts of this group courses of instruction in fracture treatment for internes have been started in many of the municipal hospitals. In Philadelphia the regional group has instructed firemen, hospital internes, and Boy Scouts in immediate traction and has obtained the necessary equipment for their ambulances. In Chicago the group gave excellent clinical demonstrations at the last meeting of the American College of Surgeons. The University of Chicago has taken over the Provident Hospital, a hospital for colored patients in

Chicago as a graduate school for negro physicians. Through the efforts of the local group fracture treatment has been emphasized, and they are making Thomas splints in their own shops at a cost of one dollar. From all over the state negro physicians are coming for postgraduate instruction. In Arizona the state group has instructed the state police so that the main highways are being supplied with splints and immediate traction is being initiated in injuries occurring along the state highways.

This, in brief, is a summary of the Committee's most important activities.

Dr. Darrach estimated a saving of \$100 per patient by the use of proper transportation of a fracture. It has been estimated that there are about 300,000 extremity fractures a year in this country. By the adoption of this method it would seem that there would be an economic saving of \$30,000,000 a year.

If we are to reduce the marked economic loss that is sustained by the average person with fractures of the extremities there must be a nation-wide campaign of medical education on the subject of fracture treatment. It has been said by Hiltzert that the average length of time that patients with fractures of the femur are kept from their normal occupation is about 14 months. This is by far too long a time. In order to improve fracture treatment public education must be carried on so that eventually we shall have stations along all highways and in main industries, where Thomas splints can be obtained readily. Groups of men must be trained in the application of these splints in a manner similar to that carried out during the war when large numbers of doughboys and stretcher-bearers were instructed in the application of immediate traction. The Thomas splint must be cheap enough and light enough so that it can be returned by parcel post to its original station or to a central warehouse.

These problems are vital to all of us. More regional groups should be organized and we need aid and advice in the formation of these groups.

STANDARD FOR MINIMUM EQUIPMENT FOR FRACTURE TREATMENT IN HOSPITALS

1. That all general hospitals be equipped to care for fractures that the minimum equipment for the transportation and emergency treatment of fractures be the following or its equivalent.

Thomas upper extremity splints Thomas lower extremity splints with traction straps, slings and buckle straps Hodgen splints coaptation splints, assorted sizes Cabot wire splints straight pieces of wood (of assorted length, width and thickness) for splints plaster-of-paris bandages, some form of overhead frame for suspension suitable X ray apparatus, including a portable machine, if practicable.

2. That it is highly desirable that one individual surgeon be responsible for the supervision of the care of fractures in each hospital service.

3. That special record sheets be used for fracture cases.

4. That a close follow up be maintained on all fracture cases for such time as necessary to establish an accurate knowledge of end results

The personnel of the Committee on Fractures is as follows

Frederic W. Bancroft, New York, Chairman

Robert H. Kennedy, New York, Secretary

Peter A. Bendixen, Davenport

Willis C. Campbell, Memphis

Isidore Cohn, New Orleans

H. Earle Conwell, Birmingham

John C. Wilson, Los Angeles

Philip D. Wilson, New York

MEDICAL SERVICE BOARD

ROBERT B. GREENOUGH, M.D. F.A.C.S. Boston, Chairman

THE Medical Service Board was authorized by the Executive Committee of the Board of Regents of the American College of Surgeons on July 15, 1933, and approved by the Board of Regents at the ensuing annual meeting. The Board was created for the purpose of formulating the general principles which could be established by the College for the guidance of its Fellows in relation to the many different projects for periodic prepayment plans for hospital and medical service, for contract medical service and for industrial and traumatic surgical services all over the country. A statement of such general principles was submitted by the Medical Service Board to the Board of Regents on June 10, 1934, and approved by them. This report was published in the June, 1934, Bulletin of the College. The inaugural address of the President of the Col-

lege at the Clinical Congress held in Boston in October 1934, dealt with this general subject.

Further reports of the Medical Service Board will appear in the quarterly Bulletins of the College in the official Journal—*SURGERY GYNECOLOGY AND OBSTETRICS* and in other channels of information.

The personnel of the Medical Service Board is as follows:

Robert B. Greenough, Boston, Chairman
 Bowman C. Crowell, Chicago, Secretary
 G. Harvey Agnew, Toronto
 Charles A. Duke, Oakland
 Franklin H. Martin, Chicago
 C. Jeff Miller, New Orleans
 Eugene H. Pool, New York
 Arthur M. Suplee, Baltimore
 J. Bentley Squier, New York
 S. Marc White, Minneapolis

BOARD ON INDUSTRIAL MEDICINE AND TRAUMATIC SURGERY

FREDERIC A. BESLEY, M.D. WAUKEGAN, ILLINOIS, Chairman

IN submitting this report of the activities and accomplishments of the Board on Industrial Medicine and Traumatic Surgery may we say that it is believed that there is a growing interest in this branch of the educational program of the College on the part of leading industrialists. Dr. Newquist and Dr. Williamson are carrying on the survey of the industrial medical organizations with some very satisfactory results. They have surveyed 1,122 such medical organizations in industry and approximately 55 per cent of them have been listed for approval. It is gratifying to note the psychological force of the desire of the leaders in industry to receive the stamp of approval of the American College of Surgeons. Obviously this fact is an important and essential factor in our educational program to secure better medical and surgical service and supervision for the army of workers in industry.

The report of Dr. Newquist, Medical Service in Industry and Workmen's Compensation Laws, has attracted a great deal of attention and favorable comment. In this connection it may be stated that the National Council of Compensation Insurance Companies extended an invitation to Dr. Martin and myself to meet with them in a conference at New York in September for the purpose of discussing mutual problems. Dr. Frederic Cotton attended this meeting with us. This Council represents both stock and mutual companies. As a result of this meeting a

committee was appointed by the Insurance Council to confer with the representatives of the College for the purpose of securing a better quality of surgical service for those injured in industry. It is believed that this movement has far reaching potentialities for achievements in this branch of our work.

Last year the Conference on Industrial Medicine and Traumatic Surgery held at the annual meeting in Chicago was very well attended and elicited a great deal of interest. We have stressed the purely scientific side of the subjects for the program for this year's meeting believing that this policy promotes the largest educational accomplishments. The sectional meetings held during the past year were favored by a very large attendance. A considerable portion of the programs were devoted to a discussion of medicine and surgery in industry, and we were rewarded by an increasing amount of interest in this subject. This is particularly true of the community health meetings where the audiences ranged in number from 5,000 to 12,000 in each city. The value of this spread of knowledge to the laity cannot be overstated. Naturally the rumors that are being circulated of what the federal government may do in connection with the relief work as it concerns medical, surgical, and hospital service for the groups of lower financial incomes, are most interesting, but any conclusions at this time must be purely speculative and would not aid us in the formulation of our

own policies. It is believed that many industrial diseases, as exemplified by silicosis, will be covered by new compensation laws comparable to those prevailing in regard to trauma. Dr. Martin is contemplating further changes in the personnel of your Board on Industrial Medicine and Traumatic Surgery so as to make it a more efficient working unit.

We appreciate the splendid support that Dr. Martin, the Fellows and this Board have given us.

MINIMUM STANDARD

1. The industrial establishment shall have an organized medical department or service with competent medical staff including consultants and also shall have adequate emergency dispensary and hospital facilities and personnel to assure efficient care of the ill and injured.

2. Membership on the medical staff shall be restricted to physicians and surgeons who are (a) graduates from an acceptable medical school, with the degree of Doctor of Medicine in good standing and licensed to practice in their respective states or provinces, (b) competent in the field of industrial medicine and traumatic surgery, (c) worthy in character and in matters of professional ethics in the latter connection the practice of the division of fees under any guise whatsoever shall be prohibited.

3. There shall be a system of accurate and complete records filed in an accessible manner such records to include particularly a report of injury or illness, description of physical findings, treatment

estimated period of disability and results, as well as other information pertinent to the case or required by statute for Workmen's Compensation claims or other purposes.

4. Patients requiring hospitalization shall be sent to institutions approved by the American College of Surgeons.

5. The medical department or service shall have general supervision over the sanitation of the plant and the health of all employees.

The personnel of our Board on Industrial Medicine and Traumatic Surgery is as follows:

Frederic A. Beasley, Waukegan, Chairman
Bowman C. Crowell, Chicago, Secretary
John E. Bacon, Miami, Arizona
Bruce D. Campbell, Detroit
Frederic J. Cotton, Boston
Samuel R. Cunningham, Oklahoma City
George H. Gehrmann, Wilmington
Donald Guthrie, Sayre
Philip H. Kreuscher, Chicago
A. D. Laxenby, Baltimore
Carey P. McCord, Cincinnati
John R. Nilsson, Omaha
Thomas G. Orr, Kansas City
W. O'Neill Sherman, Pittsburgh
Loyal A. Shoudy, Bethlehem
Ernst A. Sommer, Portland, Oregon
George W. Swift, Seattle
Frederick J. Tees, Montreal
John B. Walker, New York
S. Marx White, Minneapolis

LIST OF APPROVED MEDICAL SERVICES IN INDUSTRY

The second list of approved medical services in industry follows. This approval is granted on the basis of compliance with the Minimum Standard for Medical Service in Industry as formulated by the American College of Surgeons. There are other industrial establishments whose medical services meet the requirements of this Minimum Standard but of which time has not yet permitted a survey. The asterisk (*) indicates Provisional Approval or that the medical services so designated have accepted the minimum requirements of the College standard and are endeavoring to carry them out but for lack of time or other acceptable reasons have not been able to do so in every detail.

THE 1934 HOSPITAL STANDARDIZATION SURVEY

MALCOLM T. MACEACHERN, M.D., CHICAGO, ILLINOIS

Associate Director, American College of Surgeons

DURING the past year 3,539 hospitals were registered with the American College of Surgeons for survey. Of this number 2,483 were Fully and Provisionally Approved, thus attaining 70 per cent of all hospitals of 25 beds and over on the Approved List.

Special mention should be made of the excellent services rendered in the field survey by E. W. Williamson, M.D., Assistant Director of Hospital Activities, and Field Representatives T. R. Ponton, M.D., and F. C. Bell, M.D., men thoroughly experienced in all aspects of hospital work, who assisted hospitals in the solution of many of their problems at the time of the survey. Their detailed carefully compiled reports made a valuable addition to the fund of information which the College has on file from surveys made during the past 17 years.

The survey revealed evidence that despite economic conditions hospitals are maintaining high standards in the professional care of the patient. While continued reductions in budgets and reduction in personnel have been necessary in many instances, the morale of the hospitals generally has been splendidly maintained. Personal interests have been willingly subordinated for the benefit of the patient, and every effort has been put forth to adhere to the requirements which assure the most efficient care of the patient.

The following is an analysis of the results of the survey:

1. Hospitals of 100 beds and over

Surveyed	1649
Fully approved	1484
Percentage fully approved	90.0
Provisionally approved	77
Percentage provisionally approved	4.7
Not approved	88
Percentage not approved	5.3
Total fully and provisionally approved	1561
Total percentage approved	94.6

2. Hospitals of 50 to 99 beds

Surveyed	1051
Fully approved	505
Percentage fully approved	53.8
Provisionally approved	129
Percentage provisionally approved	12.2

Not approved	357
Percentage not approved	34.0
Total fully and provisionally approved	694
Total percentage approved	66.0

3. Hospitals of 25 to 49 beds

Surveyed	839
Fully approved	169
Percentage fully approved	20.0
Provisionally approved	59
Percentage provisionally approved	7.0
Not approved	611
Percentage not approved	73.0
Total fully and provisionally approved	228
Total percentage approved	27.2

4. Government Hospitals

(a) Army	
Surveyed	5
Fully approved	5
Percentage fully approved	100.0

(b) Navy	
Surveyed	15
Fully approved	15
Percentage fully approved	100.0

(c) Public Health Service	
Surveyed	25
Fully approved	25
Percentage fully approved	100.0

(d) Veterans Bureau	
Surveyed	73
Fully approved	73
Percentage fully approved	100.0

5. Other Countries

Thirty-one hospitals of other countries have been awarded full approval, and are included in the List of Approved Hospitals for 1934.

Summary

Total surveyed	3539
Total fully approved	2218
Total percentage fully approved	62.6
Total provisionally approved	265
Total percentage provisionally approved	7.4
Total not approved	1056
Total percentage not approved	30.0
Total fully and provisionally approved	2483
Total percentage approved	94.6
Hospitals 100 beds and over	24.6
Hospitals 50 beds and over	83.5
Hospitals 25 beds and over	70.0

MEDICAL MOTION PICTURE FILMS

J BENTLEY SQUIER, M.D., F.A.C.S. NEW YORK, NEW YORK, Chairman

THE importance of motion pictures as a means of disseminating medical knowledge has been generally accepted by the profession and there is an ever increasing interest in the work of the American College of Surgeons in co-operation with the Motion Picture Producers and Distributors of America, Inc. Films produced under this arrangement are of unusual significance as examples of the possibilities of this method as an aid in the teaching of medicine and surgery.

The College is very glad to receive medical motion picture films for review. Many have already been sent in and a card catalog is being compiled as the films are reviewed with the idea of securing detailed data concerning all available medical and surgical films. This will enable us to supply information as to what films are available on any special subject, where they can be obtained, and whether or not they are satisfactory for the purpose desired.

During the past several years improvements have been made in recording methods and in projection equipment that will be important factors in the application of talking films to the teaching of medicine and surgery. The Board on Medical Motion Picture Films is keenly interested in the development of this type of films and is maintaining close contact with the various organizations concerned with this phase of motion picture production and distribution.

Very large audiences were present at all times at the continuous daily exhibition of medical motion pictures during the 1934 Clinical Congress. The 98 films used for these demonstrations included several new talking films with both sound-on film and disc recording and also colored motion picture films.

One hundred and twenty reels of medical motion picture films have been approved by the American College of Surgeons and are available for distribution. Many additional films have been reviewed by the College, and though they have not yet been formally approved, our reviewing committees consider them to be an effective presentation of the subject matter, and the procedures shown to be of interest and value.

Information pertaining to medical motion picture films may be obtained by communicating with the College.

The Board on Medical Motion Picture Films of the College consists of the following members:

Will H. Hays, Esq. New York, Honorary President
J. Bentley Squier, New York, Chairman
Philemon E. Truesdale, Fall River, Secretary
W. W. Chipman, Montreal
George Crile, Cleveland
Bowman C. Crowell, Chicago
Malcolm T. MacEachern, Chicago
Franklin H. Martin, Chicago
Charles H. Mayo, Rochester

STATE AND PROVINCIAL SECTIONAL MEETINGS

DURING the year 1934 five large and most successful sectional meetings were held as follows

Oklahoma, Texas, Arkansas, Kansas, Missouri—Oklahoma City February 22-23
Utah, Colorado, Idaho, Wyoming—Salt Lake City February 28 March 1
Washington, Oregon, Montana, British Columbia—Spokane, March 6-7
California, Nevada—Los Angeles, March 13-14
Arizona, New Mexico—Phoenix, March 15-16.

These meetings embraced 16 states and 1 province. The following Fellows of the College and others constituted the visiting speakers

Irvin Abell, Louisville; Alfred W. Adson, Rochester; Frederic A. Beasley, Waukegan; Thomas E. Carmody, Denver; Edward H. Cary, Dallas; George Crile, Cleveland; Frank D. Dickson, Kansas City; Charles A. Dukes, Oakland; Robert B. Greenough, Boston; Robert Jolly, Houston; Edward Jackson, Denver; Thomas M. Joyce, Portland; Allen B. Kanavel, Chicago; Philip H. Krenscher, Chicago; Malcolm T. MacEachern, Chicago; Franklin H. Martin, Chicago; Howard C. Naffziger, San Francisco; Gordon B. New, Rochester; Rev. A. M. Schuitalla, St. Louis.

Most thorough and complete arrangements were made in advance according to a well worked out and tried plan. This assured the success in carrying out every detail of the various phases of the two day meetings.

A carefully thought out and well arranged program consisting of 7 phases was prepared and executed at each meeting. This was as follows

a Clinics. The local Fellows of the College, with their associates or assistants and others, conducted daily clinics from 8:30 a. m. to 12:00 noon in the approved hospitals of the city in which the meeting was being held. These were in the main operative clinics but were sometimes supplemented by dry clinics showing end-results in certain types of surgical cases. There were also pathological and X ray demonstrations. In all 5 meetings more than 200 operative clinics were held. These were of special interest and were well attended.

b Scientific Sessions. Two major scientific sessions were held at each meeting: one on the evening of the first day and the other on the afternoon of the second day. The papers at these sessions were presented by the visiting speakers and Fellows of the College from the different states in the group represented. These sessions were of special interest not only to Fellows of the College but to the medical profession at large, who were invited to attend. The average attendance at these sessions ranged from 800 to 1,000. At the same time as the scientific sessions for general surgery, the eye, ear, nose and throat

section held their special sessions, which too were largely attended and were of intense interest.

c Medical Motion Pictures. A successful innovation this year was the showing of carefully selected medical motion pictures from 12:30 noon to 2:30 p. m. daily. These sessions were of particular interest. The audiences ranged from 200 to 1,800, with an average of 900 to 1,000 despite the fact that the sessions were held at the luncheon hour. These demonstrations proved that there is a distinct place for medical motion pictures on the program of these meetings, provided a very careful selection of pictures is made.

d Hospital Conference. Throughout the 3 days at each meeting a hospital conference was held, consisting of papers, round table discussions and demonstrations dealing with administrative, medical, economic and other problems. An extensive opportunity was afforded at these meetings for round table discussions and practical demonstrations in all phases of hospital administration and standardization, thus proving beneficial to all present. The average attendance at these sessions was 150 to 200, representing in each instance the majority of the hospitals in the states included in each group.

e Programs of Public Education. During the sectional meeting an extensive and effective program of public education, as to health, scientific medicine, and hospitals, was carried on in each community where the meeting was being held. This program consisted of informative press articles, appropriate talks before community service clubs, men's and women's organizations, high school and junior college students, and radio broadcasts by the visiting speakers. Finally this program culminated in a large Community Health Meeting as the closing session on the evening of the second or last day. To this meeting the lay public was invited. A program of brief, interesting, and instructive talks on topics of vital interest, given by outstanding speakers, was well received. These talks were in understandable language and were illustrated in most part. Through careful working up of interest in each community the audiences were so large that during the series 5 overflow meetings had to be arranged. The attendance at the meetings averaged 2,000 to 25,000, an aggregate of approximately 40,000, not including several thousand in Oklahoma City, Salt Lake City and Spokane, who had to be turned away.

f Annual Meeting. At each sectional meeting, the annual meeting of the Fellows of each state was held for the purpose of electing the various state officers for the ensuing year and for the discussion of College activities.

g Credentials Committee Meetings. At each sectional meeting such state credentials committee meetings were held as were considered feasible.

THE CREDENTIALS COMMITTEES AND COMMITTEE ON HISTORY REVIEWS

THE procedure of admitting candidates to Fellowship in the American College of Surgeons requires that each candidate after filing his application be recommended by his State or Provincial Credentials Committee before proceeding further with his papers. In each State and Province there is a Credentials Committee composed of from 15 to 35 members who are Fellows of the College, elected to serve on the Committee by the Fellows of the College of their respective State or Province for a term of 2 years, one-half of the Committee being retired each year.

No candidate is admitted to Fellowship without the recommendation of his State or Provincial Credentials Committee.

The members of these committees give generously of their time and meet at a designated city in their State or Province at least once a year to review the credentials of all candidates whose applications are on file from their respective State or Province. Much credit is due these committees for their part in the work of the selection of the men who comprise our Fellowship.

After a candidate for Fellowship has been recommended by the Credentials Committee of his State or Province, he is required to submit 100 clinical records to the College, 50 in complete detail of major work done by himself and for which he is the responsible surgeon and 50 in abstract of major work at which he has assisted or which he has done himself. These records are carefully examined by the Committee on History Reviews composed of outstanding surgeons in the fields of the surgical specialties from the 4 leading medical universities in Chicago.

This year 636 sets of histories were received and of that number 594 sets or 59,400 individual histories were examined in detail by the Committee on History Reviews. The remaining 32 sets were not reviewed as the applicants had not yet received the approval of their State or Provincial Credentials

Committee. Of those reviewed 539 sets were accepted and 55 sets were not accepted. Those whose histories were not accepted have the privilege of later submitting additional histories.

Sixteen meetings were held by the Committee on History Reviews for the purpose of studying histories and during the 4 weeks preceding the Clinical Congress many additional hours were spent by the members of this committee in order that every candidate's records received this year might be reviewed.

The records, half of which were histories of cases of major operations performed by the candidates and the other half abstracts of cases which they had operated upon themselves or at which they had assisted were checked with the utmost care particularly with respect to the pre-operative data indicating the thoroughness with which the case was studied, the technique and the end-results.

The histories which were recognized as being of unusual merit were segregated and were the subject of a special review of the committee as a whole for the selection of those which were considered from the standpoint of completeness, accuracy, and form of presentation to merit special mention.

The members of the Committee on History Reviews who have served this year and to whom the College is greatly indebted for the many hours spent in the laborious work of reviewing the histories submitted are

James H. Bloomfield

THE LIBRARY AND DEPARTMENT OF LITERARY RESEARCH

THE Library and its allied Department of Literary Research have completed one more year of service to Fellows of the College and members of the medical profession.

The Library of the College was organized in 1931, and had as its nucleus the very splendid collection of volumes which had formed the library of the late Dr John B. Murphy. This collection has been augmented by the addition of such libraries as that of the late Dr Albert J. Ochsenr, a broad but well chosen and practical collection, fittingly presented by his heirs; the library of the late Dr William McDowell Meason of Mobile, Alabama, which includes eighteenth and nineteenth century volumes in French and English; back files of journals, as well as material having current reference value; and the very splendid collection of historical works and current monographs which Dr H. Winnett Orr of Lincoln, Nebraska is assembling.

In addition to the outstanding gifts above mentioned, Fellows and friends of the College have contributed many very valuable small collections and individual volumes, some consisting of treatises of historic interest and others of current reference works, especially valuable aids in the various pieces of research which are being carried on in the Department. Individual reprints and more extensive files have likewise been received.

In order that the Library may be truly representative of the work of every Fellow, that this great mass of valuable material may be preserved to posterity and that it may be available to any member of the profession who is studying similar or allied problems, every Fellow of the College is requested to contribute one copy of each of his monographs and two copies of his reprints (one for the Fellow file and one for circulation in the package library collection). Fellows are further urged to notify the Librarian of any collections which they themselves are in a position to present either now or at a later date, or which at their suggestion might be offered to the College—that these too may enter into a broader field of service and be made available to surgeons in New Zealand as well as to those in Chicago.

The availability of the Library is a factor dependent upon the services offered by the Department of Literary Research. The Department con-

sists of a small group of workers especially equipped to select reprints, compile bibliographies, and prepare abstracts and translations on medical and surgical subjects. If reprints only are desired these can be supplied without charge in package library form; bibliographies, abstracts and translations are furnished at a nominal fee.

During the past year many individual requests for research have been received, some of them being continuous surveys which have carried through the year and have required weekly or monthly reports, some pieces of research have required a series of abstracts or complete translations chosen from an extensive bibliography—others called for careful combing of all available sources for data on subjects upon which very little has been written.

Whatever the need of the individual Fellow—whether a review of the literature including extensive translations from the German, French, Italian, Spanish, Rumanian, or Scandinavian languages, or a simple bibliography compiled from the published indices—the staff is prepared to care for it efficiently. The Department has a high aim—to bring the literature of the world to the doorstep of every Fellow of the College whatever his need and wherever he may be located, and to do this expeditiously and economically.

PORTRAITS AND MEMORIALS IN THE LIBRARY

The Albert J. Ochsenr Memorial Room contains the collection of photographs assembled by the late Dr Ochsenr, founder, treasurer and past president of the College, as well as mementos of his life and work. Portraits of Dr and Mrs Elijah Dewey Harmon, physician and surgeon at Fort Dearborn in 1830, and a portrait of Mrs. Maud Mellish Wilson, who has done so much for the advancement of literary and editorial standards in medicine and surgery have recently been received. Mementos of historical significance—the mortar and pestle of the early physician and the medicine chest of the venturesome surgeon who accompanied the early French explorers along the Mississippi—these and other items of historical significance have been fittingly placed in the Library where it is hoped they will serve as an incentive for further gifts of a similar nature.

HOSPITAL STANDARDIZATION

REPORT OF THE 1934 CONFERENCE IN BOSTON

AN abstract of the papers and discussions presented at the seventeenth annual Hospital Standardization Conference held in Boston, October 15-18, 1934, is found in the following pages. Dr. William D. Haggard, past president of the College, presided.

THE NEW DEAL IN HOSPITALS

WILLIAM D. HAGGARD, M.D. Nashville. The changing conditions in the economic structure make it incumbent upon the hospital to keep step with the progress of other forces in our social fabric. The prepayment plan of hospitalization, employed in many quarters, has the new principle of allowing people of very moderate means who cannot or will not budget their incomes to make provision for sickness. The insurance principle has through all of the depression been the one thing that has stood up; it is so strongly ingrained in American institutions that it deserves a fair trial in the hospitals.

The training school for nurses should receive a great deal of thought at this conference. There is an enormous surplus of nurses in this country and this is working a hardship because of severe unemployment conditions. The plan to utilize graduate nurses wherever possible with ward service maids commends itself for serious consideration. If fewer nurses could be graduated all could receive employment; the patients would not suffer and the hospitals would not lose thereby.

Hospitals must have more regard for the rights of the patients who are often on account of illness and fear, not in a position to fend for themselves as people do in health. The principle employed in the best hotels that "the guest is always right" should be a slogan in every hospital. *The patient is always right.*

The rôle of the hospital as a finishing year for graduates in medicine should ever be borne in mind. Ample living quarters with a working library and an increased number of autopsies should be provided. The best hospital attracts the best interne. Moreover, the type and efficiency of the interne are of incalculable benefit to the hospital.

The standardization program of the College has been an inspiration and a means of stabilization to all hospitals. Medicine and nursing have anticipated the policies of the New Deal. The embodiment of a definite code of ethics in business and industry is a wise and beneficent extension of the age-old ethics which have ever been practiced and cherished by both professions.

The United States and Canada contain the best and the largest number of hospitals of any country in the world. They have lived up to their opportunities, are making great progress, and will adapt themselves to the needs of our economic condition, whatever it may be. Trustees who have the responsibility, superintendents who have the leadership, directresses of nurses who inculcate the blessed art of nursing, the physicians and surgeons, who by example and precept, combine the tender solicitous heart with gentle and willing ministrations, will in the future as in the past, make our American hospitals the greatest institutions of our civilization.

SEVENTEENTH ANNUAL HOSPITAL STANDARDIZATION REPORT

FRANKLIN H. MARTIN, M.D. Chicago. The Hospital Standardization movement has proved to be of distinct benefit not only to the hospitals which have achieved approval but also to the patient, the physician, the interne, the nurse, and the community.

Hospital Standardization assures efficient care to the patient through better medical staff organization, competent personnel, and adequate diagnostic and therapeutic facilities. Further, the writing of medical records, the examination and study of pathological specimens, the regular review and analysis of the clinical work, and many other procedures of detail and precision assure a more accurate diagnosis and rational treatment for the patient. All this means speeding up treatment through shortening the days' stay in the hospital, reducing complications, and what is more important, lowering the mortality rate.

The approved hospital provides the physician with a proper environment in which to work. Not only has he the necessary facilities at his disposal, but also a well-trained staff to assist him. Through recording the history of his patient, through proper use of the diagnostic and therapeutic facilities, the staff conference, the clinicopathological conference, and other features made available in the approved hospital, the physician is not only able to give better care to his patient, but because of organized and systematized efforts he is constantly improving his armamentarium of scientific knowledge. Finally, his own professional status is improved, for he is known as an ethical practitioner who takes a definite stand against the splitting of fees.

The hospital finds it an advantage administratively, socially and economically to be approved

which makes for a more complete and efficiently functioning organization as a whole. The minimum standard provides the hospital with fundamental principles pertaining to the best plan for assuring good professional care to patients. The carrying out of the principles of the minimum standard gives better assurance that the administration is functioning in a manner to best fulfill its purpose.

Because of its organization, equipment, and personnel the approved hospital affords the interne and the nurse better supervised experience. To this end, it is now customary for young graduates of medicine and student nurses to seek information as to which hospitals are approved.

In most instances the community is directly or indirectly interested in its hospitals. The fact that they are living up to universally acknowledged and accepted standards of professional organization and service should give the community greater confidence and pride in such institutions. Indeed, many people requiring hospitalization today seek the approved hospital knowing that such an institution is organized so as to give adequate care and efficient service to the sick and injured.

Now I have the pleasure of presenting to you the annual Hospital Standardization report for 1934.

A SUMMARY OF REPORT—1918-1934

(1) Seventeen surveys of hospitals of 100 beds and over

1918—692 hospitals surveyed
89 hospitals fully and provisionally approved
12.9 percentage approved

1934—1,649 hospitals surveyed
1,560 hospitals fully and provisionally approved
94.6 percentage approved

(2) Thirteen surveys of hospitals 50 to 99 beds

1922—812 hospitals surveyed
335 hospitals fully and provisionally approved

41.3 percentage approved
1934—1,050 hospitals surveyed
692 hospitals fully and provisionally approved
65.9 percentage approved

(3) Eleven surveys of hospitals of 25 to 49 beds

1924—307 hospitals surveyed
49 hospitals fully and provisionally approved
15.9 percentage approved

1934—839 hospitals surveyed
228 hospitals fully and provisionally approved
27.2 percentage approved

(4) Ten surveys of Government hospitals of the United States

1925—100 hospitals surveyed
90 hospitals fully and provisionally approved
90.0 percentage approved

1934—118 hospitals surveyed
118 hospitals fully and provisionally approved
100 percentage approved

Total surveyed	3,538
Total fully approved	2,209
Total percentage fully approved	62.4
Total provisionally approved	271
Total percentage provisionally approved	7.6
Total not approved	1,058
Total percentage not approved	30.0
Total fully and provisionally approved	2,480
Total percentage fully and provisionally approved	70.0
Hospitals 100 beds and over	94.6
Hospitals 50 beds and over	83.4
Hospitals 25 beds and over	70.0

GUIDING FUNDAMENTAL PRINCIPLES FOR PREPAYMENT OF HOSPITAL AND MEDICAL SERVICE

CHARLES A. DUKES M.D. Oakland There are certain definite general principles to be followed in the organization of any periodic prepayment plan which are directed toward obviating the known difficulties and dangers threatening the success of special forms of medical and hospital service. The American College of Surgeons has stated these principles as follows:

"a. Periodic prepayment plans for medical service should be free from the intervention of commercial intermediary organizations operating for profit. After deduction of the clerical costs of operation of the fund and such accumulation of reserve as may be advisable in the interests of the contributors or may be legally imposed, the full amount paid by the contributors should be available for medical and hospital services.

"b. In the interests of the patient, the organization of plans for the periodic payment of medical and hospital costs must be under the control of the medical profession in co-operation with the hospitals, and such other allied services as may be involved in the individual project, together with a group of citizens representative of the whole community and of industry who are interested in the successful operation of the plan.

"c. The principle of free choice of physician and hospital by the patient must be assured to the end that the responsibility of the individual physician to the individual patient shall always be maintained. When hospitalization is required, this choice must of necessity be limited to the physicians and surgeons who hold appointments on the staffs of the hospitals participating in the plan or to those physicians and surgeons who are acceptable to the hospital. It is further recommended that only approved hospitals be admitted to participation in such a plan.

"d. The compensation of the physician and of the hospital should be estimated with due regard to the resources available in the periodic payment fund and should be based upon the specific services rendered.

"e The organization and operation of any plan of this type must be free from any features not in accordance with the code of ethics of the medical profession, which code has been established for the protection of the patient.

"f The medical organization participating in such a plan must assume responsibility for the quality of service rendered."

The American College of Surgeons condemns the practice which involves the sale of a contract by an industrial organization to an individual physician or group of physicians for medical or hospital services for its employees. Such a practice encourages commercial competition and should, therefore, be entirely eliminated.

It is my belief that the duty of assuming leadership in this movement rests with the medical profession and the hospital field, who should take control of all measures directed to this end. They should not frown upon new methods of practice designed to meet the needs of the public for medical and hospital care. Rather they are the ones who should encourage the trial of new methods. However new plans should be carefully evaluated as to the success of their results before they are offered for general adoption. And the evaluation must be made by the medical profession and the hospital field themselves.

THE DEVELOPMENT OF PERIODIC PREPAYMENT PLANS FOR HOSPITAL CARE IN ENGLAND

SYDNEY LAMB, M B E Liverpool There are at present in Great Britain over 6½ million subscribers to British Hospital Contributory Schemes, who with their dependents comprise approximately 15 million individuals assured of hospital care in case of necessity without additional cost to themselves. In June, 1934 there were 10 million employed persons compulsorily enrolled under National Health Insurance, and as the voluntary hospital contributory funds mainly include persons insurable under the National Insurance Acts it is evident that about two-thirds of the compulsorily insured population of England are also entitled to receive hospital maintenance. The official policy of the British Hospital Contributory Schemes Association is that all persons within the national health insurance income limit should ultimately subscribe, and that the total amount of their subscriptions should be sufficient to meet the full cost of maintenance in a voluntary hospital.

It was not originally intended that the subscriptions from the workmen and people of limited means would suffice to cover the cost of the hospital care that they would receive. It was felt, however, that the contributions received in this way would be much greater in total than the meager voluntary contributions made by these people at times of hospital illness. The British Hospital Contributory Schemes were not primarily insurance plans for distributing the cost of medical care among people accustomed to paying hospital bills at the time of their sickness.

The estimated average amount paid by English contributory funds to the voluntary hospitals is about ten dollars a week, equal to about 70 per cent of the actual cost of maintenance. This does not, of course, reimburse the hospitals for their services. But when one considers that English workmen as a class paid considerably less than half the cost of services received before the contributing schemes were introduced, the voluntary hospitals may be regarded as profiting by the new plans. There is a growing consciousness that English contributory funds must accept an obligation of meeting the full cost of maintenance of contributors in voluntary hospitals. A few schemes have done so. The contributors receive free care from the attending staffs of the hospitals, although procedures are in effect in some places by which members of the hospital staffs are paid from the contributing funds.

There are approximately 150 contributory schemes in England, and nearly every voluntary hospital participates in the benefits of a contributory fund, either as a single institution with a limited number of subscribers or as one of a group of hospitals serving an entire community. The larger funds hold membership in the British Contributory Schemes Association, which includes about 130 schemes.

The contributory schemes are usually organized on a community basis, as civic movements under the sponsorship of many important agencies. A "council" guides the activities of collecting funds from subscribers and making payments to the participating hospitals. Usually there is free choice, not only among participating institutions, but among voluntary hospitals elsewhere.

The hospital contributory schemes are officially and enthusiastically endorsed by the British Medical Association, which also recommends that self-supporting plans for the middle classes be adopted throughout the country.

THE HOSPITAL IN RETROSPECT AND PROSPECT

ALFRED M. SCHWITALLA, S J Ph D, St. Louis As the gospel of standardization is the ultimate ideal of civilization, so have we striven for standardization in hospital activity. Nature preceded standardization, and standardization is regarded as an improvement on nature. In early days one hospital was not like another in atmosphere, in effectiveness, in procedures, in personnel, they differed one from another.

Today we have the satisfaction of knowing that even though there are more hospitals than ever before they are also more uniformly better. We have given to the people the service which was demanded. Even though impossible demands have been made, the hospitals have not been content merely to say "this is impossible," they have done the impossible. They have made themselves—all in one—magnificent hotels, fully equipped scientific laboratories, schools for professional training, dynamic centers of social influence, nursing homes, and in many cases placement centers. No other single group of institutions has been expected to serve so

many, such diverse, and such important needs of today's civilization. And the hospital has fully answered the demands made upon it.

This impossible task has become possible through a clearer definition of objectives, a searching work analysis the adaptation of means toward the objective, the definition of requirements, and the enforcement, largely voluntary, on the part of hospitals themselves of the standards based upon needs and the tasks to be performed to fulfill those needs. In short, it has been made possible through the process of standardization.

And yet, in our efforts to bring institutions to a uniform degree of achievement and excellence have we lost nothing at all? It is a universal law of nature that everything achieved must be paid for in sacrifice—that success here means failure somewhere else. Is it not true that when all thinking is done all problems solved, and all difficulties answered by a uniform formula the institution ceases to live actively because it has ceased to vary actively? Each new adaptation in nature is only a precursor of a succeeding adaptation adaptation to environment when it becomes static spells death to type and individual. Adaptation which progresses spells greater excellence and greater perfection. I plead therefore, for increased activity of those internal forces which express themselves in initiative resourcefulness, new ideas, new applications, the research spirit, the conscious effort to variation. I do so because I cannot but be convinced that only by paralleling progressive standardization and progressive individuality can the hospital be of the greatest service to a constantly changing local and national environment.

My hope is that hospitals may be guided by the professional organizations which are re-creating them. But my further hope is that in that re-creation there shall be as much emphasis upon the *re* as upon the *creation* the re-creation implies permanency in the midst of transition. Let each hospital know what it stands for adopt the standards and the adaptations to a changing present with prudent wisdom in accord with its individuality and continue to serve in close co-operation and harmony with other institutions like itself the needs of this changing world. The hospital type will best be preserved by preserving the hospital's individuality.

FUTURE TRENDS IN HOSPITAL MANAGEMENT AND SERVICE

BERT W. CALDWELL, M.D. Chicago There is a constant tendency to increase the service of the hospital so as to benefit a larger number of our population. Our general hospitals (a majority of which are voluntary) are serving the public by providing in patient care, out patient care and in extending home care. General hospitals are developing a program by which the character of their service will be, both in purpose and in fact general hospital service. They are opening their wards to the care of mental cases. They are offering their facilities for the

accommodation and care of tuberculous cases—particularly in the incipient stages. There is a very definite tendency to use hospital service for communicable diseases instead of sending these cases to the contagious hospitals or to the so called pest houses. In developing this program the hospitals are affording improved opportunity for the training of internes and residents in psychiatric, tuberculosis and communicable disease clinics.

There is a definite movement in hospital service to provide prenatal care and to supervise the expectant mother during the prenatal and postnatal periods. There is a definite trend amounting almost to a maternal change, in the development of adequate maternity services in the general hospitals.

Hospital service is showing a marked tendency toward a closer association with the general diagnostic clinic the treatment and prophylactic clinics.

The larger problem in hospital management today is to encourage the use of existing hospital facilities. It is the hope of the hospitals that every person suffering from any disability or disease whatsoever may have the advantage of competent hospital care in a hospital near his home, at the earliest moment, without inconvenience to himself or family and without economic disaster following his hospital care. The utilization of existing hospital facilities with each institution giving a satisfactory professional service, would solve the economic difficulties, not only of the institutions themselves, but of the members of the medical and nursing professions who staff them.

There are not sufficient hospital facilities in the metropolitan centers of the country—in the tax supported institutions, in the municipal and county general hospitals—to take care of the indigent sick who apply for admission. Had it not been for the voluntary hospitals service to the sick poor during the past 4 years, the people of this country would have suffered beyond any conceivable measure.

There must be full recognition of the fact that the changing era has brought varied problems, and that the old order of things, so long established must change to meet the new challenge and serve the best interests of public, physician, and hospital alike.

Leadership in thought and action must come from these associated groups. This leadership must develop that order of thought that system of procedure, to which the public will give its sympathetic co-operation the system that will secure a unanimity of support, and that will provide on the one hand the desired medical and hospital care for all of our people, and on the other hand a fair remuneration for the services which physicians and hospitals render.

THE PROPER INTERPRETATION OF HOSPITAL SERVICE

NEWTON E. DAVIS, D.D. Columbus, Ohio Hospital service properly interpreted, includes the very best type of organization as it relates to the manage-

ment and departmental service of the hospital. The importance of saving human life makes it necessary that the very best trained personnel be placed in charge of the organization which is responsible for the planning of the institution. For too long a time organization under trained leadership has been for tuitous, rather than required in hospital service. Too many hospitals have been merely boarding houses with some facilities for the nursing of the sick.

The modern hospital must meet all the requirements of the highest form of organization in its every department. This requisite covers trained experts in accounting, business administration, and departmental organization. The hospital is responsible for the technical service which is rendered to the patients. It is, therefore, necessary that all of the technical service such as laboratory, X-ray metabolism, and other types of special service, shall be conducted by people who are specially trained to handle the departments to which they are assigned.

A proper interpretation of hospital service as it relates to the standard of medical and surgical practice has been made by the American College of Surgeons which, through its promotion of staff organization and departmentalization of medicine and surgery has laid down fundamental principles which should be recognized and followed by every hospital in the world which expects to render the highest type of service to the patient. Every new procedure which the American College of Surgeons has set forth during the past 15 years has been a step in the right direction. But the hospitals have been slow in accepting these high requirements, and many are yet without the necessary standardization and staff program, hence are not rendering to the public the type of scientific service which they could render if they were properly standardized.

Marked advance has been made in nursing education in the United States and throughout the world in general. The insistence of the American College of Surgeons that medical and surgical practice be of the highest type has necessitated improvement in the theory and practice of nursing service. The progress made has been in keeping with the increased efficiency and effectiveness in hospital organization, technique and standardization. The hospital which merely runs a boarding school for young women, with some practical nursing service, cannot qualify today under the heading of a modern hospital.

The hospital has long passed the period of being merely a life saving institution. The proper interpretation of the modern hospital leads us to state that a hospital must, through its visiting nurses, its interne service as well as the service of the medical and surgical staff, consider the public as a vital part of its program. The relationship of the hospital to the work of public agencies, such as child welfare organizations, public health clinics, and the agencies which are working socially for the control of epidemics and communicable diseases, must be established. In this regard the hospital acts as a co-ordi-

nating unit which relates the individual who is ill to the community as a whole, and likewise brings the public into a definite social relationship with the hospital.

PRINCIPLES GOVERNING THE RELATION OF RADIOLOGISTS TO HOSPITALS

ARTHUR C. CHRISTIE, M.D., Washington, D. C.
The radiologist must be a duly licensed physician with adequate training and experience in all branches of radiology. The radiological department must be under the direction of the radiologist, and be or a qualified assistant must spend ample time therein to see every patient and to supervise every examination or treatment. His service must be such as to insure the element of medical consultation in every case examined in the department. His financial arrangements with his patients must be the same as those of other members of the staff; that is, he should fix the fee for services in each case. His financial arrangement with the hospital must be such that the hospital receives ample payment for all expense incurred by it, including a sufficient amount to cover obsolescence of apparatus. On the other hand, the hospital should not make a profit from the operation of the department nor in any way share or fix the fees of the radiologist.

Much advantage accrues to the hospital when the radiologist draws to his department a considerable percentage of his work from outside. The hospital increases its prestige by having a first-class radiological department and increases its percentage of bed occupancy through the hospitalization of patients being treated in the radiotherapy department. An additional advantage of great importance is that this is a method by which a hospital of even moderate size may have a first-class radiological department which is entirely self-supporting. Such advantages quite offset any advantage to the radiologist from his so called monopoly of the work in that hospital. It has been said that the hospital must offer to the radiologist a special "concession" but the fact is that the "concession" is mutual. The radiologist must abandon the advantages of private office practice, must be subject to the calls of emergency work, and must do a much larger percentage of charity work than he would in a private office location.

In addition to routine duties which require full time service in the hospital, the radiologist must do his part in instructing internes and residents, also in attending and taking part in all clinicopathological conferences of the staff. Furthermore, he must have frequent consultations with the hospital pathologist on cases studied by both.

The American Board of Radiology has now taken its place among the examining boards for the specialties and there are already indications that it will exert a most wholesome influence in raising the standards of radiological practice. It is confidently expected that hospital accrediting and standardization agencies will presently require that the heads

of radiological and other special departments shall be diplomates of the special examining boards, thus helping to insure high quality of service in every department.

STANDARDS FOR OBSTETRICAL SERVICE IN HOSPITALS

GEORGE W. KOSMAK, M.D., New York. When we discuss standards we must have in mind not the adoption of mere routine procedures which are applicable to all cases, but rather the adoption of those procedures which have been found by trial and experience to be the safest and most suitable. Then we must make use of them in the individual case with whatever modifications may be necessary.

It should be the aim of good obstetrics to restore the patient to her previous natural life. She may have been severely damaged by a labor accompanied by operative delivery. Her generative organs may be displaced, her genital tract lacerated, her kidneys damaged and other organs affected in such a manner that they have not returned to normal, and yet she may have failed to show these conditions through a rise of temperature. The arbitrary interpretation placed on temperature readings in most hospital services is evidently in need of revision.

The development of adequate standards for the hospital care of pregnant patients will be reflected in the home care of such women. In addition to so called standards we must consider other factors in hospitals that influence recovery. It must be admitted that the increase of hospital deliveries has not resulted in a corresponding decrease of maternal mortality and morbidity. Hospital confinements in many instances seem to have degenerated, if I may be allowed that expression into more or less artificial forms of delivery and it is worthy of note that in many sections of this country the operative incidence has increased by leaps and bounds during the past few decades. Also worthy of note is the considerable variation among individual institutions. Large public hospitals report over 90 per cent of normal deliveries, private hospitals well known and acknowledged to be excellent, show less than 50 per cent of normal deliveries.

Undoubtedly reform in hospital management of labor cases is necessary and there is equal need for developing standards which will improve the situation.

OBSTETRICAL COMPLICATIONS IN THE WOMAN'S HOSPITAL, NEW YORK, STUDIED IN ORDER TO ESTABLISH PROPER STANDARDIZATION FOR STATISTICAL PURPOSES

GEORGE GRAY WARD, M.D., BYRON H. GOFF, M.D., and ALBERT H. ALDRIDGE, M.D., New York. The usual practice of obstetrical clinics in reporting their maternal morbidity in percentages based on fixed postpartum temperature criteria is of little value for comparison, since there is no uniformity in the methods employed. At best it is only an

accurate index of possible puerperal sepsis, and takes no account of the many other serious complications which are certainly morbid." We believe the object of reporting maternal morbidity should be to establish data as to whether or not the function of bringing a child into the world has been a normal process. Therefore if a woman at any time during her pregnancy, labor, or puerperium has a condition or disease which complicates the process of child bearing so that it is not normal, it should be classed under the heading of maternal morbidity if this term is to be used, irrespective of whether the abnormal condition has a certain degree of postpartum fever as a symptom. We believe that temperature alone is an insufficient and in many instances an inaccurate criterion to use if we would correctly classify our morbid cases.

Studies of our cases show that certain patients have significant postpartum complications without any elevation of temperature and that some patients have complications with slight persistent febrile reactions who would not be considered morbid by any of the prevailing criteria.

If our purpose is to determine whether or not a certain pregnancy is normal we believe that the case should be considered throughout the entire process from the onset to the completion of the involution. Therefore, the antepartum, intrapartum, and postpartum complications should be included in statistical studies, instead of basing maternal morbidity rates on one symptom alone, namely a rise in temperature. Then we will be able to have a much better appreciation of the price of childbearing and the efficiency of our care.

For purposes of comparison and evaluation of methods, a knowledge of the temporary or permanent maternal disablement of our patients as a result of childbirth will be of more value than the estimation of possible sepsis as indicated by a single rise in temperature which is all that the "morbidity rate now in vogue means."

Our objections to present criteria for so called 'puerperal morbidity' may be summarized as follows: (1) criteria are not uniform; (2) criteria are based entirely on one symptom—rise in temperature; (3) certain patients have significant postpartum complications without any elevation of temperature; (4) certain patients have significant complications with slight persistent, febrile reactions, who are not considered 'morbid' by any of the present criteria.

We feel that there is an urgent need of a uniform standard for the determination of maternal morbidity. Such a standard should be based on consideration of all symptoms and physical signs rather than upon a single symptom. We suggest that the standard be sponsored by a national organization such as the American College of Surgeons. We would suggest that the term 'puerperal morbidity' be abandoned because of its vagueness and the conditions and diseases associated

be classified under three headings namely ante-partum, intrapartum and postpartum complications, as has become our practice at the Women's Hospital during the past year

REGULATION AND CONTROL OF OBSTETRICAL PRACTICE OF NON-STAFF PHYSICIANS IN INSTITUTIONS

SAMUEL A. CONGROVE, M.D. Jersey City In no field has the liberalization of staff practice been broader than in obstetrics. Many a general hospital the surgical service of which remains uncompromisingly closed, permits a wholly open field to anyone desiring to admit obstetrical patients. And in no other field is such untrammelled practice by physicians of little or no special competence capable of such tragic results.

Through questionnaires sent to 46 general and special hospitals, it was found that 71.4 per cent of the obstetrical services are "open" so far as private patients are concerned, only 5.7 per cent so far as public patients are concerned. Of the total services "open," only 70.4 per cent claimed control of practice.

Hospitals generally would fall into 5 classes so far as control of obstetrical practice is concerned. In the first group adherence to technique only is required. Control by indirect moral suasion only is exercised in group two. In the third class are those hospitals which control by courtesy staff grading. Control is achieved in the fourth group by restriction of appointment to courtesy staff. In group five control is by specific requirements of consultation, strongest where such requirement is universal and unequivocal.

The establishment of paper rules by no means suffices to safeguard patients. Some provision must be made for the constant contact of the institution with the patients. Thus the Margaret Hague Maternity Hospital provides through residents, young men of adequate obstetrical training and competence, who are constantly associated with the courtesy staff attendants in estimating obstetrical situations from time to time. This association is unobtrusive, tactful, and is usually welcomed by the attendant. Indeed, so dependent do some physicians become on the residents that it has been necessary to issue a specific ruling against the residents exercising a consultative function in relation to them.

Occasionally however the outside man resents the surveillance of his work and it is then necessary for the resident to act with firm decision, forbidding illicit interference if necessary pending contact with executive authority. We cannot escape the fact that hospitals do owe a direct moral responsibility to all patients admitted and must see to it that they receive medical care of high competence even if the physician of the patient's choice be not capable of giving it without the augmentation of his capacities through the consultation and assistance of others.

In any hospital, the adoption of regulations pertaining to the work of the attending staff must be reinforced by constant, active scrutiny of their

actual operation by a chief or director with definite executive power lest regulations become non-effective.

In the Margaret Hague Maternity Hospital no mother has ever died because she was permitted to remain in the sole care of an inadequately trained and inexperienced practitioner. Such a splendid record would justify every institution's maintaining rigid control of practice.

DISCUSSION

JAMES RAGLAN MILLER, M.D. Hartford I believe that hospital reports should have, each year a concise statement showing the background of the clinical material. Is the staff open or closed? What proportion of its cases are residents or non-residents? What is the proportion of residents compared to total deliveries of the city's residents? What kind of patients are represented—economically? Racially?

Before evaluating any hospital report one should know whether each physician is careless about summarizing his history on discharge or whether a benevolent despotism forces him to do truthful and accurate reporting. There is undoubtedly a drive on for more accurate and thorough control, and hospital staffs should realize that if they are unwilling or unable to exercise this control, the lay management of the hospital is going to exercise it in a more direct and perhaps less pleasant manner. At present, most of our organizations fighting the battle of maternal mortality and morbidity are controlled by committees, a method which is not calculated to produce good results.

In our community hospitals it is almost impossible to get the obstetricians to write the history and physical examination on their private patients' records. Most private patients resent a perfunctory history and physical examination done by an intern a day or two after delivery. In order to span this gap we have persuaded the Connecticut State Department of Health to print and distribute an obstetrical reference card to all physicians doing obstetrics. It is urged that the record of the first examination be sent forthwith to the hospital where confinement is to occur. This will be of service to the hospital in gauging its prospective number of births in supplying information which is now often lacking on the histories. It will also be of service to the obstetrician himself who arrives at 2:00 a.m. for example, to deliver Mrs. X and who does not recall what he found at his first examination.

If hospitals will furnish this prenatal record on their own stationery it will be much more satisfactory. The success of the "Medical Reference Card" for general cases which has been used in Connecticut for the past several years has been such as to lead us to believe that the obstetrical card will also meet a need.

THE FUNDAMENTAL PRINCIPLES UNDERLYING THE MECHANICS AND TECHNIQUE OF STERILIZATION

HURLEY T. WYATT Madison, Wisconsin Since the time that Pasteur and Lister made their out

standing contributions to surgery the development of the processes and technique of sterilization has been among the most important contributions to modern surgery. The work of surgery is largely dependent upon an abundant quantity of sterile surgical supplies. The slightest carelessness on the part of anyone who has to do with the preparation and handling of these surgical supplies may endanger the life of the patient and render the work of the most skilled surgeon of little avail. A rigid asepsis must be maintained from the time the patient enters the operating room until the surgical wound is healed and the patient discharged.

The sterilizing equipment of the hospital plays a most important part in producing and maintaining this necessary aseptic condition. For this reason the surgery and its allied departments have the right to insist that they be provided with the best and most efficient sterilizers that can be built to aid them in their important work of saving human lives. But the best sterilizers are not all that is required for after such equipment has been secured it is not only imperative that it be properly maintained but also that it be promptly and effectively serviced by competent and efficient help.

The function of the sterilizer is to kill pathogenic bacteria. Its efficiency depends entirely upon the thoroughness and completeness with which this is done. The most effective way of destroying bacteria is by coagulating or solidifying the protoplasm of the cell. This is accomplished through the medium of heat and it has been found, through laboratory experiments, that the degree of heat required will depend upon the conditions under which the heat is applied. Authoritative observers do not agree on the exact degree of heat required to kill the more resisting types of pathogenic bacteria. Their findings range from 230 degrees to 248 degrees F. This heat to be applied in the form of moist steam for a period of time ranging from 5 to 25 minutes. All will agree that the work of destruction will be effectively accomplished if the disease producing bacteria are subjected to a moist heat of 250 degrees F for a period of at least 25 minutes. To insure a conservative margin of safety the pressure sterilizers should be operated for a period of 30 minutes under a steam pressure of 18 pounds which will provide a moist heat of 255 degrees in the sterilizer chamber. This will give a temperature of 5 degrees higher applied for a period of time 5 minutes longer than that recommended by the best authority. Even this condition however will not always guarantee a complete sterilization of the dressings. A moist heat of at least 250 degrees must thoroughly penetrate to the center of the packs of dressings and be maintained there for the required period of time. Unless this is accomplished, all germ life present will not be destroyed even though there is a temperature of 255 degrees in the sterilizer chamber. It is important to know that the proper temperature and moisture reach the center of the largest pack of dressings that is being sterilized. This can be assured by packing

the dressings properly in the sterilizing chamber from which the air has been removed. By means of the vacuum ejector and other devices that have been provided on modern sterilizers, air can be removed, thus insuring the necessary penetration of the dressings.

A SCIENTIFIC ANALYSIS OF STEAM IN STERILIZING, SHOWING HOW PRECISION METHODS MAY BE SUBSTITUTED FOR THE INDEFINITE METHODS NOW IN VOGUE

WEEDEN B. UNDERWOOD, Erie, Pennsylvania
The greatest handicap encountered in establishing safe sterilizing systems is the heritage of misinformation about steam that has been handed down from the period of the introduction of steam sterilizers. Nurses have been taught to gauge sterilization by the inexact method of measurement of pressure rather than temperature.

The temperature of steam is the one bacteria destroying property. Pressure is only incidentally important. Steam is effective in sterilizing at relatively low temperatures by virtue of its moisture content. Saturated steam, as produced in the normal sterilizer, contains a definite amount of moisture. Its only variable factor with respect to its sterilizing properties is temperature. It is known that saturated steam at a temperature of 240 to 250 degrees F. corresponding to pure steam at 10 pounds pressure, will destroy all pathogenic organisms in a brief interval of time.

The relation of pressure to temperature in saturated steam is dependent upon the degree of air evacuation from the sterilizer. At 15 pounds pressure, the maximum temperature to be secured within the load of surgical supplies may vary between 212 to 250 degrees F., depending upon the degree of air evacuation.

The pressure of air in the sterilizing chamber adversely affects sterilization in four distinct ways: the maximum possible temperature will be reduced; there will be radical variations in temperature in different parts of the chamber for an appreciable time; the time required to reach a uniform degree of temperature will be seriously prolonged; the penetration power of a mixture of steam and air is far less than that of pure steam.

Sterilizers operated by pressure without measured regard for air evacuation and resulting temperatures often become hazardous. The performance may be anything from excellent to very poor but neither result is in the slightest degree indicated by the pressure gauge. Tests in hospitals show glaring inconsistencies. For example, a machine operated at 18 pounds pressure for 30 minutes developed a maximum temperature of 151 degrees F. A machine operated at 20 pounds pressure for one hour developed a maximum temperature of 220 degrees F. A machine operated at 20 to 29 pounds pressure for one hour developed a maximum temperature of 251 degrees F.

Standardization of sterilizing procedures needs to include details of loading and preparation of supplies. Rarely are there two hospitals found using identical methods. Movement of air and steam within any sterilizer is always actuated by gravity from the top toward the bottom, which fact has significant bearing on loading and preparation.

There is rather radical conflict of ideas relative to the requirements for sterilization, due probably to past inaccurate methods of gauging performance by pressure. Some authoritative body should clearly define limiting temperature and time factors, in order to bring about safe standardization and to accomplish practical, sensible reforms in sterilization procedures which will be less expensive.

OBSERVATIONS ON STERILIZATION OF DRESSINGS WITH SPECIFIC REFERENCE TO STERILIZING CHAMBER TEMPERATURES AND THEIR RELATION TO STERILIZER CHART TEMPERATURES AND CULTURES

S R D HEWITT M.D. and LYLA C BELDTYD, R.N. St John, New Brunswick. One year ago we began a study of our sterilizing practices, mainly with the idea of establishing a relationship between the temperature as recorded on the steam and pressure chart of each sterilizer, and the actual temperature as recorded by a reliable thermometer in various locations within the sterilizing chamber, more specifically within bundles in the center of drum, center of ordinary bundles, in solutions, gloves, powder, etc.

We observed that by preliminary heating of the sterilizer that is, the steam jacket, for a few minutes before proceeding with the development of vacuum and actual sterilization, it was relatively a simple matter to produce regularly a vacuum of approximately 15 inches. The vacuum was more rapidly and, what is more important, more completely obtained, by the preliminary heating. Our sterilizers are inspected every day by our chief engineer and all screens are cleaned not less frequently than once daily.

The minimum sterilizing temperature of 255 degrees F required by our procedure was not reached within the bundle in the center of the drum, in all instances, until after 30 minutes had elapsed. What was recorded for this interval held good for all subsequent intervals, up to and including 60 minutes. Theoretically therefore, our temperature chart would lead the unwary to believe that the goods to be sterilized were exposed to our required temperature for an hour. Actually we have satisfied our selves that it requires the lapse of one-half hour before that required temperature is reached in all instances.

From the observations made in 686 temperature studies, 616 of which were submitted to our pathological department for bacteriological study, we feel justified in arriving at the following conclusions: (1) we have satisfied ourselves that our sterilization practices are eminently safe. (2) we believe that we can obtain more complete vacuum by preliminary

heating of the jacket, (3) we believe it should be possible to reduce the time required for our sterilizing procedures. (4) there is a fairly considerable and consistent discrepancy between the thermometer intra-drum, bundle etc. temperatures and the temperature on the steam chart in the majority of instances, during the early periods of sterilization. (5) we are unable to satisfy ourselves that there is any method as safe and accurate as that of utilizing a thermometer within bundles. (6) there is a very definite irregularity of behavior of steam penetration, under identical conditions so far as we can produce them. For example, of the intra-drum temperatures reported at sterilizing level, by thermometer there is a spread of 19 degrees, one bundle showing 235 degrees, another bundle 254 degrees. At 20 minutes, just taking this interval as an example, we find that this group study did not, relatively speaking, do as well from the temperature standpoint as those studied at 15 minutes. As expected, the discrepancies gradually became less, until at the end of 30 minutes, speaking of drums again, our final records show only a difference of 3 or 5 minutes.

CHECKING AND CONTROLLING POSTOPERATIVE INFECTIONS

HAROLD L. FOSS M.D. Danville, Pennsylvania. Some form of complication accompanies a certain number of all surgical operations in the best of our hospitals even when the most modern technique is used. However such complications should be kept at an irreducible minimum. Possibly even with the greatest care, 5 per cent of operations will be followed by some complication.

Of all complications approximately two-thirds have to do with the wounds themselves. Fortunately most are innocuous and are the result of contamination with the ordinary skin coed. A high percentage of wound infections following "clean operations" is inexcusable. Catgut plays a certain rôle, but relatively few complications are the result of infection introduced by the suture material alone.

Most postoperative wound complications result from actual "breaks" in surgical technique, the types and varieties of which are legion. Some of the more common are insufficient sterilization of instruments, gloves, and gowns; insufficient preparation of the hands of surgeons and nurses; carelessness on the part of the surgeons or nurses in the handling prior to coming to the operating room, of infected material—all too frequently infection is transmitted as the result of unintentional carelessness in matters of personal hygiene. Sporadic occurrences of wound complications resulting from infection with the hemolytic streptococcus are frequently traceable to certain members of the operating room personnel who are carriers and who constantly harbor the organisms in their upper air passages. A careful masking of the mouth and nose of each person in the operating room will eliminate this source of infection.

The incidence of postoperative wound infections varies according to the location of the operating

room. For example on the ground floor it will be relatively high while on the top floor it will be relatively low. It likewise varies according to the degree of scrupulous cleanliness with which the room is kept, the number of people in the room and the extent of disturbance.

Every well conducted hospital should have a careful record of postoperative complications, particularly a list of postoperative wound complications and infections. If they occur consistently with a frequency above the normal or irreducible minimum the fact should be made known immediately to the superintendent the chief of staff or some individual in authority whose duty it should be to take steps to correct the evil. Furthermore, every operating room employee and every surgeon operating in the institution should be constantly aware of the presence of such a record and should be willing and ready whenever the incidence of trouble with operative wounds is excessive to institute a thorough investigation with the object of improving conditions promptly. A surgeon who regularly has a high incidence of infected wounds following operations performed on clean cases should not be long tolerated in the modern hospital, and by the same token the superintendent who being aware of an abnormal incidence of wound infections on a certain service does nothing about it, should be replaced by someone more conscientious and competent. Civilization has advanced too far to permit such laxity. The clean surgical patient has a right to expect a clean hospital a clean surgeon and, following the completion of his operation, a clean postoperative wound.

SOME SOCIAL AND PERSONAL PROBLEMS OF SURGICAL PATIENTS

IDA M. CANNON Boston Medical social workers whose professional function is concentrated on the patient as a person and on his human relationships wish that it might be made clearer to surgeons that our interest includes not only the surgical end result, but more especially what is happening after the surgical end results are dismissed from attention. We believe that the patient would benefit from more satisfactory co-operation between surgery and social service in this area.

The relation of character and personality to the experience of sickness has always been a subject of major interest to social workers. We have considered that our service was primarily concerned with character under adversity and that sickness and pain and facing of death and prolonged crippling disease brought special tests of character.

We are hearing increasingly these days of the introduction of psychiatry into the general hospital, the purpose of which is better understanding not only of functional disease but also of the functional factor so often present in organic disease. The contribution of psychiatry to medicine is only beginning to be appreciated, or at least so it seems to many of us social workers who are turning to psychiatry for deeper insight into human motives and the conflict

ing forces in personality. May not psychiatry have something to give to a better understanding of the patient in the surgical ward where we see at work the forces of fear and loneliness and bitterness which have been called retrogressions of spiritual growth? I believe that both psychiatry and religion should have something to contribute to these problems.

It is the psychic shock in surgical experience that would seem to need exploration. At least we may become more skillful in preparing the patient who for the first time faces the startling experience in the hospital ward and operating room which to us are so very familiar and congenial. Surgeons often state that their skill is to give nature freedom to do her mysterious work of repair. The patient must of course be the one who must finally struggle through the personal problems. Collectively may we not attain finer methods of freeing the patient to make more satisfactory repair of the psychic wound? May we look forward to the time when evaluation of end results will cover not only the physical findings and the functional capacity such as are noted in the end results of fracture cases but will also seriously consider the capacity of the patient to carry on in his human relations? I realize that personality and character offer probably the greatest variables but this serves to emphasize the necessity for more earnest consideration of the problem.

EXPERIENCE WITH A HOSPITAL FOR PEOPLE OF MODERATE MEANS

MORGAN J. RHEES, M.D. Boston The Baker Memorial, the department of the Massachusetts General Hospital for patients of moderate means, has now been in operation for 4½ years. An increasing number of patients has been cared for each year. The Baker Memorial plan is summarized as—

- 1 The offering of moderate rates for bed care and for special services in a hospital unit large enough to facilitate economical administration.

- 2 Co-operation with the medical staff whereby moderate fees are charged for professional services.

- 3 The unifying, by consent of the medical staff of all financial dealings with the patient under the hospital administration so that the patient is not presented with two or more independent bills for hospital and professional care, respectively but with a single bill collected by the hospital, which in turn passes over to the physician his agreed fee.

- 4 An endeavor to minimize the amount and cost of special nursing.

- 5 An effort to provide all the service at cost, without charity and without profit.

The rates charged for board and other services are designed to cover the costs, with the building occupied to about two-thirds of capacity. A sufficient number of floor nurses is provided so that special nursing is seldom necessary and is allowed only if a patient needs more care than can be given by the floor.

Practice in the Baker Memorial is limited to members of the staff of the Massachusetts General Hospi-

tal and the Massachusetts Eye and Ear Infirmary. The staff has agreed to a schedule of limited professional fees, with a maximum of \$150, regardless of the length of stay or number of physicians involved. The hospital undertakes to see that only patients of moderate means, who cannot afford to pay higher fees, are admitted. Of 100 consecutive admissions the average income was \$2,772. 80 per cent had incomes less than \$3,000. 54 per cent less than \$2,000. Requests for admissions from people with incomes less than moderate are much more numerous than from those who might be considered as well-to-do. Ninety-seven per cent of the patients are referred to the hospitals by members of the staff; only 3 per cent come directly from other doctors.

The Baker Memorial has not yet become self-supporting. It is hoped that it will be when occupied to about two-thirds of capacity. The first 4 years had a deficit averaging \$63,000 a year. For the first 3 years the Julius Rosenwald Fund agreed to pay half the deficit. The balance and the entire deficit after the third year must be carried by the charitable funds of the Massachusetts General Hospital. In 1934 there has been a greater occupancy and a smaller deficit. The coincidence of increased occupancy with increased business activity would seem to indicate that with economic recovery the Baker Memorial will be able to pay its way.

A TRIAL OF THE EIGHT HOUR DAY FOR HOSPITAL SPECIAL NURSES

SALLY JOHNSON, R.N. Boston. A review of a trial period of the 8 hour day for hospital special nurses was made during the 5 months, May through September, 1934, at the Massachusetts General Hospital and the Massachusetts Eye and Ear Infirmary. A comparison with 1933 was difficult, as the necessary data were not recorded, but based upon the statistics which were available, the following statements are of interest.

During the trial period, there was a daily average in the two institutions combined of 731 patients. The number of calls for special nurses which were filled was 3,778. The morning period of service is from 7:00 a.m. to 3:00 p.m., the evening from 3:00 p.m. to 11:00 p.m., the night from 11:00 p.m. to 7:00 a.m. The charge for each period is \$4.50 to the nurse, and 25 cents to the hospital for each of two meals, making a total cost to the patient of \$15 for 24 hours of service. Under the new system, the hospital itself has thus far not added to its personnel. The changes in cost to the patient with the 8 hour plan were reported to be as follows: General Hospital, average ward patient who was specialied, an increase of \$16.05 per patient per month (part of the increase in 1934 was due to the special apparatus required for several patients in for long periods of special care); Phillips House (private pavilion) increase per patient of \$8.50 per month; private pavilion of Eye and Ear Infirmary increase per patient, \$7.78 per month; Baker Memorial (for persons of moderate means) a decrease per patient of \$1.08 per month.

In reply to a questionnaire sent to the 3 groups most vitally concerned, 135 nurses gave unanimous approval of the 8 hour day. Of 100 physicians, 6 reserved an expression of opinion, 13 did not approve. 6 approved with minor reservations, 75 fully approved. 250 patients replied as follows—13 had no basis for comparison, 30 disapproved, 212 approved without reservation. The data of comparative earnings and days of employment seem to indicate an increase in both figures. However, it must be remembered that few nurses had accurate figures for 1933 so that the number of studies was small, and that a nurse now has to pay for one meal daily which formerly was furnished.

Reliable records of the employment of individual nurses show that the 8 hour day has brought speed of employment. At the Baker Memorial, during a period of 5 months in 1933, 149 nurses were employed, while during the comparable number of months in 1934, 258 nurses were employed. There was some increase in the daily census of patients, but not sufficient to produce this spread of employment. In the Phillips House during 5 months of 1933, 180 nurses were employed during the comparable 5 months in 1934, 223 were employed. The daily census was only slightly higher in 1934. In the general hospital in 1933, 122 nurses were employed during the 5 months during the comparable 5 months of 1934, 193 nurses had employment. There was practically no change in the daily census of patients.

Based on 18 years of interviewing prospective applicants to schools of nursing, I am of the opinion that an 8 hour day for hospital special nurses will do much to reduce the parents' objections to nursing as a vocation for their daughters. I believe that this change will bring more young women who possess integrity of character, an acceptable social background, attributes of desirable personality and a higher level of education, to the profession of nursing. Any plan which will tend to accomplish this result is worthy of serious consideration, for it will improve nursing from the standpoint of the hospital, of the nurse, of the physician, and of the patient.

HOW I, AS A HOSPITAL TRUSTEE, VIEW MY RESPONSIBILITY

IDA M. CANNON, Boston. The first duty of a trustee is to accept as the central purpose of the hospital the skilled and ready care of the sick and injured. In so far as the hospital provides an opportunity for education of internes and nurses, this educational function should be secondary to the care of the patient. It is a happy fact that the higher the quality of consideration and care of the patient, the better will be the basis for good teaching of doctors and nurses. The trustee must be interested in listening to any serious complaints about service. The sympathetic hearing of such complaints often results in the issue disappearing into thin air; explanations can often be made that disarm the critic. If there is ground for complaint the duty of the trustee is to express gratitude for having the situation brought to

official attention and to make every effort to have it corrected.

Next to obligation to the patient is loyalty to the professional groups within the hospital. There should be respect for each position in the organization. There should be scrupulous care not to undermine the authority of those placed in positions of authority and responsibility. Deference is due the professional groups when questions concerning professional service are brought to the board of trustees for consideration.

Community relations should be of special concern to the trustees. It should be remembered that in accepting the appointment of trustee one is not only a special representative and interpreter of the hospital to the community but also a special representative of the community to the hospital. There should be a sensitive interest in a program for the hospital that will take into account the changing needs of the community. There should be a feeling of responsibility for keeping abreast of the most progressive thought concerning hospital administration.

The position of a hospital trustee is one of those elastic responsibilities that cannot be measured in hours of service. The board is invariably made up of busy people who must fit this extra service into already crowded hours. It therefore rests with each trustee to see the full scope of the responsibility accepted by the group making up the board of trustees. Within that joint responsibility there is the obligation on each trustee to see what special contribution he can make so that collectively there may be within the board an integration of special contributions.

HOW I, AS A HOSPITAL PRESIDENT DISCHARGE MY DUTIES

FULLER BARNES Bristol Connecticut I have always felt that experience is one of the best teachers, and that the president of a hospital if he is at all active, must necessarily have an intelligent knowledge of all departments and of as much of the work as possible.

Each year in our institution the trustees appoint 8 members to an executive committee, 5 laymen and 3 doctors. The medical and surgical staffs, which are well organized nominate 3 of their own members to this committee each year. The executive committee meets once every month with the superintendent. Each member knows exactly what he is responsible for and takes an active interest in seeing that the various departments function effectively. This relieves the president of much worry and is an ideal situation from his standpoint. There is a separate committee for the training school of which the president is chairman.

The trustees of the hospital meet at the call of the president, once a year for the annual meeting. They are men of standing and means in the community who have the interest of the hospital at heart, but their positions are more honorary than active. Each year they go over the progress of the

hospital and to a large extent follow the recommendations of the president and the executive committee for the following year.

I feel it my duty to work closely with the finance member of our executive committee. I endeavor to attend the session of the committee of the Connecticut Legislature having to do with appropriations to hospitals, and attempt to keep the appropriation in line with what we feel we should have. As a trustee of the Community Chest I endeavor to see that the hospital receives a budget allowance adequate to meet the running needs of the hospital. The budget committee is composed of the chairman of the executive committee, the finance member and the president. We run on a very strict budget which is checked each month. Bristol Hospital has never been in debt.

I have always taken a great interest in keeping the public informed as to what the hospital and training school are doing endeavoring to see that we get publicity of the proper sort and that the public knows items of interest in regard to its hospital. For this reason we distribute widely our annual report.

I consider it the duty of every active president to visit his hospital at least once every 10 days, oftener if possible to talk over current events with the superintendent who appreciates moral support and a close sympathetic understanding. While visiting the hospital I endeavor to call on as many patients as possible and talk with the nurses and doctors in an effort to maintain the spirit of co-operation and friendliness which is so essential.

Having delegated authority whether to a committee, the superintendent, or an employee, the president should never go over their heads, but work through them in whatever questions may arise. He must not delegate too much to his subordinates and should not permit problems which should be settled to remain unsettled. The president must maintain a capable and friendly organization in which all committees and employees work together in close harmony so that no problems are allowed to get beyond control.

HOW I AS A TRUSTEE, JUDGE THE EFFICIENCY OF OUR HOSPITAL

INGERSOLL BOWDITCH, Boston The trustees are responsible for the policies of the hospital if they allow the superintendent or the staff to dictate these policies efficiency will be decreased. Trustees may be sure that their hospital is not lacking in efficiency if it is approved by the American College of Surgeons approved for internship by the American Medical Association, and its school of nursing approved by the State Board of Registration.

In studying the efficiency of a hospital the book keeping department is an excellent place to start. The daily record of patients will give an idea of whether the doctors are making use of hospital facilities. The treasurer's monthly statements will show if expenses are being met. Statistics from the

record room files will reveal many important facts. A trustee may learn what the mortality is in maternal cases and what percentage of patients are being discharged relieved or not relieved. Another good place to check efficiency is in the boiler room. This can be under the supervision, in addition to that of the superintendent of a trustee who has a technical knowledge of how boilers should be fired.

Doctors are generally very free in their criticisms of the way a hospital is run and by talking with them informally a great deal can be learned. At least once a year at my hospital the medical and surgical staffs meet with the trustees and are given an opportunity to make suggestions. At least one member of the staff is on the executive committee and he is able to keep the committee informed as to how the doctors feel in respect to the efficiency of the hospital.

It is a good plan to place each trustee on a different committee so that he can come into contact with special activities. The monthly meetings are made more interesting by the reports from each trustee who is able to impart knowledge concerning a specific department.

An excellent way to learn whether a hospital is filling the needs of a community is by reading letters written to the superintendent by patients who have been discharged. Another means is by judging the type of internes. If a hospital can get internes who were graduated near the head of their class at medical school it is safe to say that the institution will be efficient.

If a trustee is willing to give the time, he can easily learn whether his hospital is being run efficiently—not only by attending the trustees' meetings but by visiting the hospital at various times, day or night, by being on friendly terms with the doctors and all those who are connected with the hospital, from the superintendent to the orderly and by being a member of at least one committee of the trustees. The more you know about your hospital the more pleasure you get out of being a trustee.

TUMOR CLINIC RECORDS

JAMES T. NIX, M.D. New Orleans. It is possible that the solution of the cancer problem rests with the tumor clinic record. To be adequate it is essential that the record have completeness and accuracy coupled with simplicity. Long questionnaires are undesirable because they lack flexibility that is, adaptability to the individual case. They tend to stress form rather than content and make for perfunctory stereotyped, mediocre records. Nevertheless, there are certain necessary points of information which must be contained routinely and unless furnished on the printed page these points may easily be overlooked and neglected, much to the detriment of the record. Uniformity and standardization are therefore desirable and necessary but they must be tempered with sufficient elasticity to preserve the individual features of every case.

The following is an outline of an adequate tumor clinic record.

1. General identification data advantageously assembled on a printed page.
2. Summary sheet, serving as a guide to the remainder of the folio and intended to furnish the essential points in the case record at one glance.
3. Statistical form containing information abstracted from the record and tabulated for the purposes of clinical research.
4. Complete history and record of physical examination at the time of the first visit to the clinic, as exhaustive and personal as those taken in a surgical or medical service.
5. Reports of all roentgen-ray studies with the corresponding plate numbers.
6. Record of all clinical laboratory examinations, especially the Wassermann reaction and hemograms.
7. Reports of the pathological department on tissue sections either from biopsy or operative specimens, or both, with the dates and corresponding slide and specimen numbers.
8. Graphic information including photographs in chronological order, photomicrographs whenever possible and diagrams made to scale of the lesion and the region affected.
9. Social service information.
10. Record of the treatment instituted, whether surgery or radiation or a combination of both.
11. Follow-up records, embracing the progress notes made by members of the medical staff at the patient's periodic visits to the clinic, and entries made on the record by the social worker.
12. Miscellaneous, including the various "release forms" employed at different hospitals.

Two points deserve special emphasis—the need for complete radiation records and the value of good graphic sheets. X-ray and radium treatment sheets must have complete information. They should have a diagram of the part and lesion radiated showing the actual position of radiant foci in addition to a statement of the method and the type of radiation employed, the type of container and its strength, and the filter used, the duration of exposure, the surface dose, and size of the tumor and distance from the skin.

THE USE OF THE NATIONAL NOMENCLATURE

H. B. LOGIE, M.D., New York. While hospital staffs are exhorted to keep adequate records in order that they may be approved, the ultimate purpose of record keeping is not just approval, but the promotion of mutual instruction and self-education. Before the hospital record system can be perfected and attain its proper importance the attitude of the hospital physician in writing case histories must be altered.

The wholesome principle of the *Standard Nomenclature of Diseases* is the point of view illustrated on every page that disease is a process, not a thing. Adherence to this principle preaches in its quiet way

the necessity of determining the course of events which constitute the morbid process. It tends to dignify the process of diagnosing and naming diseases, since names take on a live meaning when they are chosen only after a clear and logical process of clinical thinking. Between the lines of the *Nomenclature* is the constant exhortation to the clinician to define his case completely in clinical terms and the warning is there that the names of the specialities of disease are not diagnoses. Moreover the clinician finds that many of his pet terms are either cloaks for ignorance or merely partial diagnoses and therefore not diagnoses at all. Here, then, is a task for the thinking man and not a disagreeable duty to be relegated to the most immature of the hospital's physicians or even to lay employees. The question two years ago was whether physicians would shirk the added responsibility or would respond to the challenge. The answer can now be given. Diagnoses are so much more comprehensive and complete in many of the hospitals using the *Nomenclature* that were it not for the speed and accuracy of the coding system, record rooms would have difficulty keeping pace with them. Cases are diagnosed more fully and the record of the hospital's experience is kept more faithfully not because of rules and regulations, but because the physicians wish them so. Thus, then, is the foundation upon which the National Conference has come to build that clinical thinking is at the root of all medical practice, diagnostic, therapeutic, and prognostic and that the improvement of any hospital depends in large measure upon how fully its physicians realize that the record of its successes and errors and failures, and of the mark of advancing medicine in its practice must be an open book for those who write its history and those who follow.

The National Conference on Nomenclature of Disease in the beginning contemplated only a nomenclature comprehensive enough to serve as a national standard. It soon learned however that nothing but the most accurate possible classification of diseases would serve as a standard for all, and that the system to be set up must be adaptable to an accurate, complete and readily usable system of record keeping. So far as has been possible, the best medical thought in this country and to some extent in other countries, has been put at the disposal of the Conference. The Conference has been compelled to hew as closely as possible to the line of clinical accuracy. Moreover had it not determined at the outset that the nomenclature was to be clinical and not merely anatomical or physiological, it would have been compelled by the parallelogram of forces to adopt this broader view of disease

coupled with a proficiency in shorthand and typing is preferable. The minimum requirements should be set at 2 years of college training and should include a foreign language, preferably Latin. With this background the student should be not less than 21 years of age. She should be required to present a certificate of good health. The make-up of her character and personality should be studied for a sufficient length of time through observation, and her recommendations examined closely, to ascertain whether she possesses the necessary poise and other essentials. Upon completion of the course the student should be required to pass with credit a comprehensive examination prepared by the Board of Registration of the Association of Record Librarians.

The length of the course should be a period of not less than 6 months, 8 months is preferable. Instructors must be selected with extraordinary care and have at least the same educational background expected of the student coupled of course with the advantages in experience which practical application during a period of service has given. The time of such experience has been set at not less than 5 years of actual hospital work. A person should be endowed with a convincing forcefulness and a dignified earnestness in order to qualify as an instructor for only to the extent to which she possesses such characteristics can she be assured of gaining the confidence and respect of her students.

Hospitals in which the student is to receive training may be divided into two classes. First, those connected with universities which can give the educational background at the same time that the student is being given practical experience. Second, those which without a university connection will give the practical training to the student who is already equipped with the necessary educational qualifications.

Any hospital applying for the privilege of training students should be a general hospital with a capacity of not less than 250 beds. It should have an out-patient department, an accredited interne service, a school of nursing, a social service department, and, most important of all, it must possess all the standard facilities required by the American Hospital Association, the American Medical Association, and the American College of Surgeons. The hospital should charge a reasonable tuition or fee for the training and should not treat the student as an apprentice, but provide her with sufficient closely supervised, practical work to permit the actual application of classroom theory.

Thus, we are endeavoring to establish a new milestone in the progress of our profession, to lift it to the plane its importance justifies, and to create standards which will assure its continued development and expansion as a necessary collateral branch of the medical arts. It is our sincere hope and wish that we find a co-operative tolerant attitude on the part of all our associates, and that through such co-operation our efforts may lead to the favorable results which our sincerity of purpose warrants.

BASIC PRINCIPLES IN THE TRAINING OF RECORD LIBRARIANS

JESSIE N HARNED Rochester New York In addition to suitable personality which is most essential a record librarian must have the proper cultural and educational prerequisites. College training

ORGANIZATION AND MANAGEMENT OF A MEDICAL RECORDS DEPARTMENT IN A SISTERS HOSPITAL

Sister M. PATRICIA, O.S.B. B.S. Duluth. When the Standardization program of the American College of Surgeons began in 1918, a new era opened for all hospitals, and in a special sense, for hospitals under the management of the various religious Sisterhoods. It was with the spirit of their founder that the Sisters set about to comply with the requirements of the College. One of the most difficult requirements to be met was "That accurate and complete records be written for all patients and filed in an accessible manner in the hospital."

A well organized medical records department should have a chart of organization. This includes the board of directors, superintendent, medical staff, medical records librarian assistants, and at times, student librarians. In institutions where student librarians are trained affiliation with some nearby college is necessary. Record librarians should hold membership in the Association of Record Librarians of North America.

The major functions of a records department are to contribute accurate data for the scientific study of disease by the staff and internes, and consequently to improve the care of the sick. In conducting research, records are essential. In the treatment of any given disease the records on that disease show what was done for the patient, the reason why it was done, and whether the method of treatment produced the best results possible. Records also give an analysis of the physicians' work in the hospital which information can be used in making appointments to the hospital staff. Staff meetings and pathological conferences could not be held without making use of records.

In our experience the best location for the records room is in the main line of passage. It should be centrally located because of the contact which the records librarian must have with all departments, especially with the regular and visiting staff. It has been advised to place the department as near the staff room as possible because doctors will be likely to consult the records if they are within easy reach.

An efficient filing system is of importance to the hospital and to its medical work. There should be simplicity of arrangement, reference material should be easily accessible, and the scientific classification must be correct. The storage of records has been a problem in most of our hospitals, because of the difficulty in finding a place where the charts can be conveniently and safely kept. The unit system has been acclaimed the best system of numbering and filing records. In the operation of the unit system a designated person should be available during the night to look up charts of previous hospitalization.

The sooner a record is written after the patient is admitted, the greater its accuracy. The supervision of records should also begin as early as possible. Some hospitals use a check system whereby the charts are inspected daily by the personnel of the

records department, and deficiencies noted on colored tags placed on the chart.

No chart is complete unless a follow-up record of the case after the patient has left the hospital is included. It is not enough to file the record when the patient is discharged; one must follow him up for 1 or 2 years to ascertain if the diagnosis of his illness was correct and the treatment successful.

Finally an efficient records department requires the efforts and interest of the entire hospital personnel.

ROUND TABLE CONFERENCE. PROBLEMS CONCERNED WITH CLINICAL RECORDS WITH SPECIAL DISCUSSION OF USES OF CLINICAL RECORDS

Conducted by ALLAN CRAIG, M.D. Torrington, Connecticut

The most outstanding of the many interesting problems relative to clinical records which were discussed at this conference were the following:

1. The prompt writing of records was unanimously voted as one of the difficulties in almost all hospitals. Several speakers emphasized the uselessness of records long delayed and the dangers of records written after the patient had left the hospital. This brought up the question of how far the hospital might go in enforcing record regulations. One hospital record librarian said that members of the staff had been suspended for carelessness in this respect, but that they had returned with the honest attempt to comply with the regulations.

2. Should nurses be permitted to take case histories? This question naturally brought some division of opinion between the larger and the smaller institutions. It was, however, the consensus that case histories when taken by a nurse do not always reveal the true status of affairs either regarding family history or personal history, these being confidential matters between the physician and the patient. It was the general opinion that nurses should not be permitted to write case histories, and that the only person who should and could get a reliable history would be the physician or his assistant. This discussion brought out the necessity of ethical confidence not only in the writing of case records but also in their handling and in their reviews.

3. The use of case records for purposes of research and investigation was discussed at length. Should the physician be permitted to take the records from the hospital? Some of those present indicated that under special circumstances a physician should be permitted to take the records out of the hospital for the purpose of research or investigation or in order to prepare his cases for Fellowship in the American College of Surgeons or the American College of Physicians. It was the general consensus, however, that the records should not be removed from the hospital for any purpose except on subpoena of the court. It was also the majority view that the hospital should provide a place where physicians on the

staff might review records without taking them out of the institution. The question of whether or not the records department should assist physicians and surgeons in preparing their records for the College of Physicians and College of Surgeons was discussed and it was decided that every assistance possible should be rendered these men, and that the records should be typewritten. However the physician should make some arrangement with the records department of the hospital for carrying out this particular work.

4 The permission of one physician to review the records of another was discussed. It was thought by some that the physician should obtain not only the permission of the physician who wrote the record but also the permission of the patient. In reviewing cases for the compilation of statistics or medical or surgical papers, it was felt that this would handicap the physician writing the paper and if the name of the patient were not revealed, the consent of the physician would be sufficient.

OBSTETRICAL DEPARTMENT IN A GENERAL HOSPITAL

CHARLES J. KICKHAM M.D. Boston The maternity department in St. Elizabeth's Hospital is segregated on one floor which contains wards and nurseries, as well as delivery admission, and isolation rooms. None but a maternity patient is ever admitted to this department even though the maternity beds may be in great part unoccupied and though other departments are turning away patients for lack of available space.

Our obstetrical staff consists of a chief, three senior and three junior obstetricians, and a house interne who while on obstetrical service is not permitted to attend any other type of patient. The house patients from the prenatal clinic comprise a large number of the admissions, but any member of the hospital staff may send patients for delivery thus the actual care and delivery of cases in our obstetrical department are distributed among a fairly large group of men.

Upon admission patients are sent to the admitting room. If they are prenatal cases their record is sent up from the clinic. Complications, such as kidney or cardiac disease, are given special attention, but if no complications are noted our routine is to keep these patients in the waiting room during their labor period. Here a general physical examination is made and recorded on admission. The nurse records blood pressure, pulse, duration and interval of labor pains, rupture or non rupture of membranes, any bleeding or abnormal vaginal discharge, action of the fetal heart, and effects of any pre-delivery sedatives which have been ordered. Particular attention is paid to the fetal heart, record of which is taken as a routine every half hour or hour depending upon the stage of labor. Rectal examinations are made on admission and at intervals as indicated and findings recorded. No vaginal examinations are made except upon special order.

Shortly after admission the patient is shaved and scrubbed, and an enema given unless contra indicated for any reason. As termination of labor approaches, the patient is brought to the delivery room and delivered under strictly aseptic conditions. The delivery suite, which includes a waiting room is isolated from wards and corridors.

Nothing but aseptic towels and draperies are used in the waiting and delivery rooms, thus keeping them in a highly aseptic condition. When patients are nursing babies they are obliged to use masks so as to prevent transmission of respiratory infection from mother to baby. Patients after being transferred to the wards are given instructions about danger of infection, and are cautioned about handling or contaminating the parts or carrying infection from below to nipples and breast by the fingers. Routine care is given to vaginal and rectal section especially after bowel movements. Vulva pads are used but left loose so as not to back up lochia. The breasts are watched with care, particularly the nipples, for cracks and between nursings are covered with sterile waxed paper as a result of this constant watchfulness we are happy to report that for many years we have not had a breast abscess. We use the rotating nursery method, and all maternal such as crib coverings, babies clothing etc. is changed frequently and nothing but sterile linen used. If any patient runs a temperature of more than 99.8 degrees for more than 48 hours, she is automatically transferred to the isolation ward. We have been fortunate in having no sepsis for some years, and our mortality rate is very low. As another safeguard, visitors are scrutinized as much as possible, and if observed to have any infection such as a cough or to be using a handkerchief for coryza, the dangers are explained and they are asked not to visit. At no time are children allowed to visit.

All nurses are watched for any type of infection. Nurses and internes in the obstetrical delivery room are those who have already had their operating room training. During the training year all nurses are given special courses by the staff on obstetrical and gynecological subjects.

CARE OF EMERGENCIES

CORNELIUS J. O'LEARY M.D. Boston Being situated in a district through which some of the main arteries of travel pass into the city and being within easy range of a number of small industrial plants, St. Elizabeth's Hospital has a busy accident department. We are prepared to handle accidents during all hours of the day or night. The department is in charge of one of the Sisters who is a trained nurse. To assist her she always has one or more of the student nurses.

When the accident case arrives the patient is taken at once into a room immediately adjoining the admittance door. The house officer whose sole work during a period of 3 months is to handle accident cases, is summoned at once. We have a rotating system for our internes at the hospital, and they

take charge of the accident service only after completing all their other services, the interne in charge of this department is always well trained.

If the accident is slight the interne himself cares for it—always, however, giving orders for the patient's return on the following morning at which time the visiting surgeon sees him and approves what the interne has done or institutes such other treatment as may be necessary.

If the accident is severe the visiting house surgeon is summoned at once. The arrangement at our hospital is for 6 surgeons to take 2 months each on house cases. During the time of their house service they are also on service for serious accidents. When the surgeon has viewed the patient he admits him to the hospital if he believes such procedure necessary. Fracture cases, if severe are referred to the orthopedic department.

In all cases of severe head injuries patients are X-rayed at once. Regardless of the findings, the patient is advised to remain in the hospital for a period of at least 24 hours. Having specialists in eye, ear, nose and throat work, all of whom are not far from the institution and who are expected to respond at once to any urgent call from the hospital, we are prepared to take care of such cases under the guidance of skillful doctors.

No operative work is done in the accident room nor are blood transfusions given there. Our operating rooms, under 24 hour supervision of graduate nurses, are so near at hand that the patient can be transferred thereto without any loss of time if major operative work is necessary. Everything required for emergency work in such cases as drownings, asphyxiations, monoxide poisonings, and the like, are to be found right at hand in the accident room. With such arrangement and equipment we have no difficulty in successfully treating the large number of emergency cases which we are called upon to handle.

OUT PATIENT DEPARTMENT

REV THOMAS J. BRENNAN, Boston. I have been unable to determine historically the genesis of the out-patient department. Probably someone in the vicinity of a hospital who was in need dropped in and asked if some doctor would see him, which request was very charitably granted. Others, bearing of the service, probably did likewise and soon the hospital saw the desirability of establishing such a service for the needy. This is merely a theoretical explanation.

The organization of the out-patient department at St. Elizabeth's follows along the lines of out-patient departments in general hospitals. More than 17,000 patients were treated in this department during the past year.

To cite an editorial from the current *Medical Digest* which discussed an article entitled "The Plight of the Doctor." It is now customary even in hospitals maintained by public and private con-

tributions, to make small charges for medical service in the so called free clinics. But it has never become customary for the doctor to be paid for his work in these clinics. Once a free patient, always a free patient. Doctors have observed that they rarely ever are visited again by a patient after that patient has acquired the free clinic habit. Most of those who first entered free clinics because of the economic depression never again will patronize their family doctor.

It is the duty of the hospital to protect the doctor from unworthy cases—those who dishonestly abuse the service of the free clinic. While good social service departments can do much in this matter there are always hidden resources which even these departments cannot investigate. Would it not then be a good idea to make each patient coming to the free clinic bring a letter from a local physician stating that the case is a worthy one? In this way the physician would at least have an opportunity to offer free care to the patient, and he may even be remunerated at a much later date. Under present arrangements he is denied this opportunity.

MATERNAL CARE

A series of practical demonstrations on maternal care, supplemented by motion pictures, was conducted at the Boston Lying In Hospital by LOUISE S. ZUTTER, R.N., superintendent, and heads of departments. The program embraced the following features:

"Admission of Patient to Clinic," ERMINE COMEA, R.N. "Physical Examination of Patient," HAROLD M. TEEL, M.D. "Care of Patient in Labor," Care of Patient in Delivery Room, Immediate Post Partum Care," ETHEL STEWART, R.N. and assistants, "Care of Newborn, Formula Room," BERNICE DENIORD, R.N. "Care of Premature Infant," DOROTHY SOLOMON, R.N. "Care of Post Partum Patient," EDITH CARPENTER, R.N. "Care of Isolated or Septic Patient," FLORENCE BOSTOCK, R.N. "Post Partum Clinic," FLORENCE SWANSON, R.N.

A round table conference was conducted by ROBERT JOLLY, Houston, superintendent, Memorial Hospital, and president, American Hospital Association, on "Administration, Professional, and Economic Problems," which constituted a clearing house for all questions arising out of the deliberations of the previous sessions, in addition to a special program of fifty important hospital questions.

Demonstrations and round table discussions in hospital standardization and administration were conducted at the Beth Israel Hospital by CHARLES F. WILKINSKY, M.D., director and heads of departments, including the following: The Training of Internes in the Social Aspects of Illness," ERMINE COMEA "Food of Hospital Patients," MARGARET MOORE "Some Nursing Problems in a General Hospital," JOSEPHINE A. MULVILLE, R.N. "Applications of Business Principles in the Management of Hospitals," CHARLES F. WILKINSKY, M.D.

PRECANCEROUS AND CARCINOID LESIONS OF THE CERVIX UTERI

WITH COMMENTS ON THE SCHILLER TEST

ERLE HENRIKSEN M.D. BALTIMORE, MARYLAND

From the Gynecological Department of the Johns Hopkins Hospital and University

IN the great majority of cases the diagnosis of carcinoma is simple enough either clinically or pathologically and microscopic examination is only confirmatory. In the early and "borderline" cases however, the microscope must play the decisive rôle. To wage an effective fight against cancer, moreover, we must not only be familiar with the characteristics of early cancer but we must learn something more about lesions now loosely spoken of as "precancerous." This term was first used by Dubreuilh in 1896 and has been widely adopted. It is undoubtedly a good descriptive term if applied as it should be, only to those processes which may but do not necessarily, become malignant. It should not be construed as indicating that the lesion in question represents the preliminary stages of cancer, though it is quite possible that some of them do. As long as we do not know the cause of cancer a study of these lesions and of their possibly malignant potentialities offers a new and fertile field for the gynecological pathologist and may be expected to yield much in the way of early treatment and prophylaxis of cancer.

We have recently completed a study of material from the cervixes of 50 individuals who have been treated conservatively in our department, in an endeavor to correlate as accurately as possible the histological picture and the subsequent clinical course. Micro-

scopically the cervixes all showed evidence of increased cellular activity i.e., mitoses, hyperchromatosis, polymorphia, and hyperplasia of the basal layer, without, however, any evidence of invasion. Indeed all the cytological characteristics of cancer were in evidence except epithelial heterotopia. Recent examinations have shown in spite of the cancer like cell changes in the original lesions, no tendency to the subsequent development of cancer.

Normal cervix. The accepted description of the normal histological picture of the cervix varies so markedly that it is difficult to obtain sections of the epithelium conforming to the textbook descriptions. The distinction between the three accepted strata is definite. The basal layer has a picket fence appearance with an undisturbed nuclear polarity. Mitoses and hyperchromatosis are more frequently present than most observers have noted but these are merely suggestive of expected natural cellular changes necessary for the processes of growth and repair.

The thickness of the epithelial layer is apparently independent of the age of the adult patient and we have noticed no constant histological changes in the pregnant cervix. Inflammatory processes seem to alter the basal layer bringing about an apparently increased cellular activity. Hot douches, cauterizations, and local therapy also produce a distorted histological picture (Fig. 2).

Metaplasia The value of serial sections of biopsy material is fully demonstrated in cases of so called metaplasia or epidermization. Though in some instances the cytological changes resulting from the inflammatory lesions do present a perplexing picture the cellular activity in some of the chronically infected cervixes has frequently led to erroneous interpretations, and probably accounts for some so called 5 year cures. In most instances the benign invasion by the squamous epithelium is innocuous in appearance and in no way resembles the ruthless invasion of the malignant growth. Cell nests and columns of squamous cells (Fig 3) apparently lying free of surface attachment may tend to confuse the picture. A full appreciation of the mechanism of this process simplifies its interpretation and lessens the probability of errors in diagnosis. The individual cells in most instances display none of the characteristic cytological features associated with malignancy. The round cell infiltration is also less marked though this reaction is far from dependable. Mitoses and hyperchromatosis are not uncommon and not infrequently the changes are so marked as to suggest a cancerous process.

That in the majority of cases so called metaplasia is not a precursor of cancer is accepted. However the presence of this process does imply a chronic irritation and conservative corrective therapy is indicated. Without

doubt a few of these lesions do develop into malignant processes, but it is not possible with our present information to differentiate the ones that will remain benign from those possessing malignant potentialities.

Leucoplacia Hinselmann's work with the colposcope has revived our interest in the leucoplacia like changes in the cervical epithelium and has also created a new field for possible diagnostic errors. Simple curetting of the cervix for microscopical study as originally suggested by Schiller does not yield sufficient tissue for the diagnosis of this process, as the individual cellular changes may too closely simulate the cells of cancer. Again the value of serial sectioning of biopsy specimen is to be emphasized.

The process develops most frequently at the site of transition between the squamous and columnar epithelium though it is not rare to find the entire cervix sprinkled (Plate I, Fig 6) with the small white or grayish white plaques. Microscopically the epithelium is more compact and varies in thickness. There is decided basal layer hyperplasia with changes in the nuclear polarity. Mitoses may be of both the normal and the pathological types, though they may be very sparse. The subepithelial round cell response also varies and may at times be entirely lacking. We have not noticed the subepithelial hyalinization which is so commonly seen in leucoplacic processes elsewhere. In those cases with marked stromal reaction it is frequently difficult to trace the basal line and the presence of invasive tendencies may be simulated. As Schiller has shown there is usually a sharp transition from the normal epithelium to the area of leucoplacia. This line of demarcation is also prominent in other conditions as we shall describe later. Leucoplacia elsewhere is considered genuinely a precancerous lesion, but whether this applies to the cervix is certainly debatable. The histological criterion accepted by some include changes characteristic of definite malignancy except that invasion is not present. Several observers claim to have observed cases in which cancer has developed within an area previously shown to be leucoplacic. We have not been fortunate enough to encounter any similar instances.

Fig 1 From a 19 year old nullipara (Plate I, Fig 1). The three strata are well defined and the basal line is intact with equal nuclear polarity. No stromal reaction.

Fig. 2

Fig. 3

Fig. 4

Fig. 5

Fig. 2 An unusual abrupt change between the loosely packed squamous layer on one side and a more compact layer; this differs from the transitional line in certain other conditions in that it is vertical. This patient had received a prolonged course of local therapy to the cervix.

Fig. 3 Benign epidermization with nests of squamous cells, rare mitoses, and no suggestion of malignancy.

Fig. 4 The epidermization process has replaced the cylindrical elements in an orderly fashion, except at one point there is an apparent break in the basal membrane.

Fig. 5 High power of Figure 4 showing increased cellular activity with mitoses, many hyperchromatic nuclei, and no definite limiting layer. Six years after this biopsy was taken the patient shows no evidence of cancer.

However we do believe that the present evidence is insufficient to place this lesion in the same class, as regards cancer potentiality with the leucoplaciac found elsewhere.

Carcinoma Whether or not the metaplastic and leucoplaciac processes of the cervix are likely to develop into true cancer is undecided. And yet we do not feel justified in permitting certain lesions to remain untreated because of scientific interest in their future course. The following case shows that carcinoma, here a basal cell type may develop in metaplastic area.

The cervix (Plate I Fig. 3) was deeply lacerated with a duck bill appearance three

small plaques were present just within what was formerly the external os. Following the application of the iodine solution the two plaques on the anterior lip showed some absorption of the iodine and microscopically a local epithelial hypertrophy. The small plaque on the posterior lip, however did not absorb the iodine and stood out sharply against the mahogany background. Biopsy was not performed as an interposition operation with cervical amputation was indicated. Serial sections through the posterior lip showed a small malignant growth measuring 1 millimeter in diameter and originating in an area

Fig 6 Changes in the cervical canal depicting the columnar elements replaced by squamous cells. Beneath the pale, normal appearing cells is noted the increasingly broad layer of darker stained cells, this layer supplants the paler cells entirely and assumes an appearance suggesting cancerous activity

of definite metaplasia. This patient is being examined each month and as yet has shown no tendency to recurrence.

Other interesting cervical lesions. So far as we know the microscopical cervical changes in the 2 following cases have received little or no attention in the literature. In 1912 Bowen described similar changes in the skin in an article titled "Precancerous Dermatoses. Chronic Atypical Epithelial Proliferation" and the skin lesion described is accepted by most dermatologists as Bowen's disease. The

Fig 7 High power showing the marked cellular changes. Mitoses and hyperchromatosis are frequent. This patient shows no evidence of cancer after a period of 18 months has elapsed

acceptance of this as a nosological entity from the standpoint of etiology and pathogenesis is still debated as is its relationship to the so called extramammary Paget's disease. Though the histological changes in our cases do not altogether fulfill the cytological criteria specified by Bowen, Darier, Jessner and others, the similarity is striking enough to bear comparison.

CASE 1 (Plate I Fig 2) In October 1933 a 24 year old negroess was examined for vaginal bleeding, later found to be the result of endometrial hyperplasia. Inspection of the cervix revealed a small cyst like area on the anterior lip suggestive of an

Fig 8 Biopsy from a cervix of a 45 year old woman with prodisentia of 2 years standing. Marked thickening of the squamous layer with metaplasia. The basal layer shows definite hyperplasia, increased compactness of the strata, and increased cellular activity with abundant stromal infiltration

Fig 9 Higher power showing typical mitoses with polymorphism and hyperchromatosis. The cervix was excised following an interposition operation and 4 years after this operation had been performed there is no change present which might be regarded as suggestive of cancer

Fig. 10 A specimen removed from the anterior lip of the cervix in 1930. There is no evidence of cancer on recent examination. This is definitely of the leucoplastic group, showing epidermal thickening, increased compactness of the basal and transitional layers. Several small epidermal buds seemingly lying free of surface attachments are the result of angular sectioning. There is no evidence of invasion.

ordinary nabothian cyst. However, the iodine was not absorbed as readily as expected and the biopsy showed changes suggesting early malignancy with perplexing cellular changes. Radical measures were deemed unnecessary as it was thought that the entire growth was included in the biopsy. The location of the area was also considered to speak against malignant growth as the accepted site of predilection for both cancer and leucoplacia is near the external os or at the junction of the squamous and columnar cell layers.

This case is being carefully watched in our outpatient department and at a recent examination shows no recurrence of the white areas and the cervix has always readily absorbed the iodine.

Fig. 12 Section of a polyp removed in 1930 showing marked basal hyperplasia with all the cellular changes characteristic of cancer. However invasion has not taken place.

Fig. 11 High power of the epidermal bud shows many mitotic figures; however the entire picture is that of a benign process with increased cellular activity.

CASE 2 There is no evidence of invasion in either of these cases. The relative lack of stromal reaction, with the edema and hyalinization in the second case removes this lesion from the category of accepted cancer. The true nature of this lesion is not known: are we dealing with an unusual form of cancer or of leucoplacia or a pro-cancer with a new pathological and clinical entity? Two cases are not enough to warrant conclusions as to their true etiology or pathogenesis. We are following with interest the first case which was treated conservatively but unfortunately a panhysterectomy was performed on the second case.

Intracervical carcinoma Though not an instance of early malignancy, we have included the following case not only to illustrate the value of the Schiller test in some cases but

Fig. 13 High power showing both normal and pathological mitoses. There is also a moderate polymorphism. The stromal reaction is not marked. The patient on recent examination shows no tendency to cervical cancer.

Fig. 14. The line of transition between the squamous cells in the more normal epithelium and the carcinoma area is sharp and clearly demonstrates the mode of malignant extension.

also because of the unusual nature of the malignant extension.

CASE EL. A 60 year old negroes was registered with the complaint of vaginal bleeding of 3 weeks duration. At examination there was no apparent bleeding and the pelvis was essentially of the normal senile type. On inspection the cervix was found to be smooth and firm with a wide velvet red margin about the external os, which did not bleed following manipulation. This was interpreted as a typical erosion. A cotton swab passed up into the cervical canal did not elicit bleeding. Following the application of the iodine solution a small grayish-white plaque about 3 millimeters in diameter was noted at the right lower angle. A biopsy specimen showed a slight thickening of the epithelial layer with a small area sharply demarcated from the more

Fig. 15. Higher power drawing of B in Figure 14 showing more clearly the cellular differences between the two areas.

normal appearing tissue and strongly suggestive of leucoplakia. One small nest of squamous cells, however made us suspicious of malignancy though various observers differed and some considered it benign. In view of the patient's history of post-menopausal bleeding, age, and the suggestive microscopical picture, a panhysterectomy was advised.

LAHM SCHILLER TEST

It was noted by Lahm in 1927 that the portio vaginalis of the cervix displayed certain absorptive qualities following the application of Lugol's iodine solution. The chemical basis for this absorptive ability has been attributed to the presence of a glycogen-like substance in the cells of the spinal layer of the cervical epithelium. The clinical value of the test was further elaborated by Schiller following a thorough study of different lesions and their reactions. However the correct interpretation of the test is not a matter of simplicity as there are many modifying factors present even in the normal cervix and many that may serve to confuse the final picture.

In the crowded out patient department the application of the iodine solution with a sponge is not only time consuming but exceedingly inconvenient. To overcome this disadvantage we use a bulb atomizer with the cervix well exposed and clean. It is relatively simple to spray the entire cervix under direct vision. The excess solution is removed with the speculum following the examination.

Fig. 16. High power drawing of C in Figure 14. Gland cells are also present, but are more numerous in the surface area. This is the earliest definite carcinoma of the cervix we have seen, and is of special interest in that it appears in an area of metaplasia commonly regarded as benign.

Fig. 17 An oval epidermal bud with marked karyokinetic asymmetrical division, peculiar clumping of the nuclei, and vacuolization of the cells. There is a moderate parakeratosis, with nuclei broken up into very small granules. A few large cells with numerous large nuclear fragments can be seen scattered through the entire epithelial surface. The picture is suggestive of those changes associated with arsenical keratosis and is not dissimilar to roentgen-ray dermatitis

Previous digital examination with an oiled or soaped glove will tend to confuse the picture. When the cervix is covered with blood or discharge spraying the cervix with a moderately strong solution of potassium permanganate and carefully wiping with a soft wet sponge is sufficient to ensure a clean surface. Care must be exercised in manipulation so as not to traumatize the cervical epithelium thus removing the glycogen-containing cells and distorting the picture.

The normal surface of the pars vaginalis absorbs the iodine evenly and assumes a dark mahogany color. Nabothian follicles as a rule also absorb readily, but not infrequently stain to a lesser extent. In case of eversion with the columnar epithelium presenting the stain is not absorbed by the everted mucosa and the color is a pinkish red (Plate I Fig. 6). This is disappointing as the test is thus of no value in cases of adenocarcinoma. However this type of growth is relatively infrequent occurring only in 1 of 25 cases in our series.

The areas of erosion vary in relation to the intensity of the inflammatory reaction (Plate I Fig. 5). The more acute the inflammatory process the deeper the absorption, as the leucocytes rich in glycogen readily take up the iodine.

Fig. 18 High power showing the definite intracellular oedema and hyalinization, parakeratosis, hyperkeratosis, multinucleated giant cells with clumped nuclei, and a few pathological mitoses. There is no evidence of an invasive tendency and the cells are for the most part embryonal in character

We have recently noticed certain variations in the pregnant cervix. In three young primigravidae in the early months of pregnancy, and with cervixes normal in appearance the iodine was absorbed readily in two instances and taken up very lightly in the third. This was repeated a number of times with the same result each time. Biopsy failed to reveal any histological clue for this variability. We have also noted in apparently normal cervixes following supravaginal hysterectomies that some of the cervixes fail to absorb as readily as before the operation.

As a rule the areas of metaplasia do absorb the iodine as do cases of advanced malignancy in which there is a marked secondary infection. With late cases having suspicious nodules in the vaginal vault, the application

Fig. 19 Small grayish-white elevated plaque not unlike the preceding case in location and gross appearance. The pitted area is the site of the biopsy

Fig. 20. The biopsy specimen showing an edematous subepithelial layer with hyalinization, which is not uncommon in leucoplakia elsewhere in the body, also a scant round cell reaction. The transition between the obviously normal epithelium and the abnormal area is not as marked in this drawing as in Figure 22, but the transition in the stroma is surprisingly sharp, and extends through the entire area of the process.

of the iodine may serve to outline the areas of malignant extension.

Leucoplakic areas are occasionally visible without the aid of the iodine test as small white or grayish white plaques. But these vary from day to day in their gross appearance and whether this chameleon like ability affects the absorptive power is not known. However we have observed several cases in which the histological picture was that of typical leuco-

Fig. 21. High power view from the center of the process illustrating the peculiarly large giant-like cells with pathological appearing mitotic figures, the intracellular edema and keratinization. The latter is more apparent in Figure 23. There are also a few abnormal mitoses. The intracellular edema alone differentiates this process from extramammary Paget's disease, where intercellular edema is present with the large characteristic Paget cells.

plakia, while the gross picture even with the aid of the iodine was negative.

Small areas of carcinoma of the squamous cell type present a picture identical with that of leucoplakia, so that the test is not specific for malignancy but serves rather as an aid in selecting the site for biopsy.

Though this test is routinely applied to every patient in our dispensary and fully 25 per cent of the cases have been checked histologically, we do not at all feel that it is infallible. The use of the colposcope as advised by Hinselmann and others does magnify the gross picture but with good exposure and

Fig. 23. Higher power to illustrate the intracellular edema and keratinization, which is especially marked in this case.

Fig. 24 Normal appearing senile cervix with typical erosion about the external os the biopsy site at the lower right angle. On gross examination of the cervix after the removal of the specimen there was no suggestion of cancer

Fig. 25 Longitudinal section through the uterus, showing a definite well circumscribed intracervical carcinoma with the canal relatively free of the usual friable projections commonly present in malignancies of the cervix. Extending from the primary growth in the cervix is a thin layer of cancer of the squamous cell type which covers the entire endometrial surface but does not extend out into the tubes.

light the added cumbersome and expensive equipment is not indispensable. We have picked up several early cases of true carcinoma which undoubtedly would have been missed without the aid of the test. An advantage of the test is the simplicity of its application especially with the aid of the atomizer. The test also necessitates a thorough study of the cervix with good exposure and light a point in pelvic examination frequently overlooked. It is the only subsidiary diagnostic aid we have at present and warrants a thorough and fair trial.

BIOPSIES

In view of the admitted difficulties in the microscopical diagnosis of early carcinoma of the cervix the amount of tissue for study must be sufficient to include not only the suspected area but also some of the apparently normal tissue. For satisfactory interpretation of the histological picture an aggregate view of the changes must be obtained. Diagnosis based on the individual cellular changes is hazardous especially when the tissue is scant in amount. One section from the area in doubt frequently misses the suspected process while serial sections of the specimen will not uncommonly reveal the real nature of the lesion. We have been impressed with this on many occasions and routinely follow this procedure.

The dangers of infection dissemination or stimulation of the tumor growth and hemorrhages are apparently not as dangerous as they were once considered by many. In spite of any possible risks the data obtained more than counterbalances them. That stimulation of

the tumor growth occurs is a moot point there is no proof that the growth is accelerated and animal experiments show no change in the growth rate following trauma. Neither have we noted any infections following the biopsy either with the punch forceps or with the scalpel. Three days after taking a biopsy from a normal cervix the wound is usually completely healed. In most cases the site of biopsy is touched with phenol or silver nitrate. Hemorrhage except in advanced cases rarely occurs and at most amounts to only a slight

Fig. 26 Low power drawing showing the relation of the squamous cell cancer spreading like "cake frosting" (cancer of the "zuckerguss" type) over the entire endometrial surface the endometrial glands are of the senile type. The growth has not invaded the myometrium

venous ooze. An important factor in taking the biopsy is immediate fixation for it has been shown that the alkaline secretions of the cervix bring about a definite fading of the nuclear particles and thus the resultant microscopical picture is hazy. Immediate freezing and staining is the ideal method but when permanent serial sections are desired from a small bit of tissue this procedure is difficult and undependable except in the hands of an expert.

The divergence of opinion as to the diagnosis in very early carcinoma of the cervix is disheartening many still seem to cling to the older concepts of cellular confusion so characteristic of the late stages. At the other extreme are those who scent malignancy wherever there is a departure from the accepted normal of cellular activity. In order to appreciate fully the pathology of the cervix one must be especially equipped to diagnose the very early case. To attain this knowledge one must possess a familiarity with all the various cellular changes checked by careful follow up studies in each case. Merely to call the changes suspicious or doubtfully malignant is of little aid to the clinician who wishes to be informed that the lesion is either benign or malignant. If the pathologist can not decide either way the responsibility reverts to the clinician though when such doubt exists the wise plan is often to defer active treatment until the question can be definitely settled for such a slight delay will rarely endanger the patient.

SUMMARY AND CONCLUSIONS

The microscopic diagnosis of cervical cancer will not be improved until both the clinician and the pathologist learn more about such pseudomalignant and possible pre-malignant lesions of the cervix as have been discussed.

Mitotic figures are occasionally seen in the basal layer of the normal cervical epithelium and are to be looked upon as evidence of the normal growth and repair of the cervix.

Cervical lesions may be spoken of as "pre-cancerous" when it is understood that the term implies they might though not necessarily become cancerous. The microscopical picture of these lesions is less perplexing if the mechanism of development is understood. That cancer does originate in the so called metaplasias is illustrated by 1 case.

Leucoplakia of the cervix is a pathological entity which may show cellular changes suggestive of cancer though invasion is always lacking.

Two cases showing microscopical changes similar to both Bowen's disease and extra mammary Paget's disease a condition rarely if ever described in the cervix.

An interesting case is described of intra cervical carcinoma diagnosed with the aid of the Schiller test, and in which the malignant growth extended over the entire endometrial surface of the uterus.

The importance of biopsy is indisputable but its value is increased if the specimen is immediately fixed and serial sections are made. Serial sections are of especial importance in cases of suspected early cancer.

The application of Lugol's solution with the atomizer simplifies the test. The Schiller test is undoubtedly of some value in the diagnosis of early cancer whether it is a specific for the absence of the cancer is questionable.

To Dr. Thomas S. Cullen and Dr. Emil Novak we acknowledge with sincerest gratitude our indebtedness for the valuable assistance in the preparation of this paper. We also wish to express our gratitude to Mr. Milton Koenig for the splendid photomicrographs, to Mr. Leon Schlosberg for the colored plate, and to Mr. M. D. Dietrich and Mr. J. O. Osgood for the drawings.

FULMINANT SINUS DISEASE

STUDY OF THE PATHOGENESIS¹

FRANCIS L LEDERER, M.D. F.A.C.S. CHICAGO, ILLINOIS

THE nose with its accessory nasal sinuses is capable of giving rise to interesting and formidable pictures indicative of local and general disease. Acute osteomyelitis of the maxilla, especially in infants occurs with sufficient frequency to lead to considerable theorizing as to its etiology and therapy. In studying the complicating factors and sequelae of this condition we have tried to trace the ways by which it becomes associated with acute suppuration of the accessory sinuses of the nose.

The literature is replete with case reports of fulminant nasal sinus involvement, in these the various complications, the possible etiological factors, and the treatment applicable in each instance are discussed. The majority of reports name thrombophlebitis as the usual route of extension and stress conservatism in treatment. The autopsy material has been surprisingly meager, clinical evidence or biopsy specimens were usually taken as final. We were fortunately able to study serially sections made through the head of an infant 3 weeks of age who as the history indicates developed a fulminating sinus infection manifested by external swellings about the face and associated with a concealed thrombus in the cavernous sinus. Even without the history, a careful study of the histological series would make it quite possible to trace in chronological order the entire course of the disease.

CLINICOPATHOLOGICAL FEATURES
OF FULMINANT SINUS DISEASE

Fulminating sinus disease always has been considered a formidable condition because of the anatomical relationship between the sinuses and the surrounding structures. Endocranial, auricular, ocular, dental, and systemic involvement may result from extension of sinus infections. In speaking of a fulminating type of sinus infection, the writer refers to sinus disease which manifests itself by swellings about the face, osseous involvement, and

intracranial signs and symptoms, other authors prefer to look upon this type as merely acute sinusitis. Yet the spread of infection by direct extension (continuity of structure), or through the lymphatics or the blood stream and along the facial planes, foramina, and perineural sheaths is well recognized, the pathological alterations which occur depend upon the special anatomy of the region.

The subject is of sufficient importance to note briefly the several possible pathways by which an infection in the sinuses of the nose may involve other structures. Since the particular type of sinus disease under consideration occurs so frequently in infants and young children certain anatomical and developmental features demand special consideration. Aside from traumatic possibilities, infections may invade the cranium through congenital dehiscences—the ethmoidmaxillary suture or openings in the bony wall of the lamina papyracea or in the orbital wall of the maxilla. That infection can travel by way of the perineural sheaths requires some explanation. It is not generally known apparently, that there is no direct connection between the lymphatic vessels of the peripheral parts and the intradural structures and that the sheaths surrounding the olfactory nerves although they are continuous with the piaarachnoid, do not contain lymph. Spread by lymphatics has heretofore been thought to be the common method of extension but the anatomical facts suggest otherwise (18).

Direct invasion of the vessel wall by way of communicating veins is probably the commonest mode of extension. The nose is particularly rich in venous drainage. The septic thrombus proceeding by way of the diploic veins may produce a retrograde infective thrombophlebitis or periphlebitis. Involvement of the cavernous sinus may occur through various venous routes according to which areas of the nose and its surroundings are diseased. Foci in the anterior part of the

nose may extend to the sinus by way of the angular vein, whereas those in the interior of the nose and sinuses go through the ethmoidal veins. Such a case from my clinic was recently reported. In this instance a bilateral cavernous sinus thrombosis developed following a submucous resection of the nasal septum (7). Infected foci in the superior maxilla may spread by way of the pterygoid plexus. The anastomotic venous radicles also permit infection to be transmitted between these different channels. Caries and inflammatory erosion of bone (osteoclasia) may result from extreme pressure by inflammatory products or these products may cause a separation of the bone from its mucous membrane and mucoperiosteum.

Purulent inflammation of the nose especially during influenza or any of the acute infectious fevers, may cause a reaction of the tissue which interferes with the normal ventilation of the sinuses. There may be anatomical obstructions or there may be swollen turbinates impinging upon the septum even though the nose gives little evidence of inflammation shows no bulging of the wall of the nasal cavity and maintains a free flow of secretion. Usually it is the ethmoid sinuses that are involved although a pansinusitis on the same side may occur. The ethmoid cells are well developed early in childhood and since acute upper respiratory tract infections are frequent, involvement of these sinuses is by no means rare. In addition the vascular

and lymphatic development is greater in children than in adults (3). The mucosa becomes edematous and the underlying periosteum becomes infiltrated (periosteitis); the bone bleeds freely (osteitis) during operative intervention. The structures overlying or neighboring the bone may become swollen and the bone itself become sequestered (caries).

CLINICAL PICTURE

A unilateral swelling of the upper lid is characteristic of frontal involvement (in children past the age of 5 years) a swollen lower lid is associated with ethmoid cell disease or both lids may be swollen in a combined involvement (Fig. 1). The lids become infiltrated (periocular and orbital cellulitis) and occasionally the infection may localize and form an abscess (orbital abscess—Fig. 2) or even break down to form a fistula (caries or necrosis—Fig. 3). Similar swellings, at first brawny and later soft may occur over the frontal area and the cheek. Inflammation usually causes a thickening of the periosteum at the medial wall of the orbit leading to a red painful swelling near the inner canthus of the eye. There may also be pain localized to the involved area or referred to other parts of the head. The temperature may vary from 98 to 105 degrees F. Strangely enough, one may find a violent external manifestation in an individual who is not acutely ill. Figure 4 shows a rather striking picture of objective inflammatory reaction, without much sub-

Fig. 2. left. An abscess of the lid which resulted from a periorbital cellulitis. This condition necessitated external drainage in addition to shrinkage and intranasal drainage.

Fig. 3. In this patient, as the result of a caries with abscess formation a fistula from the floor of the frontal sinus occurred. An external approach, with the removal of sequestrated bone when the acute process subsided, led to a resolution of the process.

Fig. 4. A striking picture is presented by such a marked objective reaction, as shown in this case, without much subjective response. In this patient the appearance was even more exaggerated because of the application of tincture of iodine to the forehead by the patient himself. The therapy in this instance, infraction of the middle turbinate and irrigation of the frontal sinus, favorably influenced the picture within 48 hours.

jective response. The eyeball itself may remain normal but occasionally becomes proptosed; the bulbar and palpebral conjunctivae are decidedly chemotic. Motion of the eye may be limited owing to external rectus paresis or impaired motility of the extra-ocular muscles. When the proptosis becomes so great as to prevent the lids from covering the eye, corneal ulcers may form. A papilloedema may also occur in such cases. The predilection for the maxilla is explained on the basis of its larger size, more rigid construction, attachment to the skull—favoring a more frequent reception of trauma—and greater blood supply around areas of ossification. Unerupted teeth represent areas of greater vascularity which may determine metastatic infection.

Saeger, reviewing 67 cases of orbital inflammations collected from the literature and one of his own, concluded that sinus disease is one of the most common causes of orbital inflammations in children. He quoted Coakley, Harke, Oppikofer, Wertheim and Wolff as showing by autopsies that the sinuses of children may be readily involved. Others believe that children do not have the essential predisposition for rhinogenic orbital inflammation that adults have. Theisen, in a study of 31 cases from his service in an infants hospital, found the sinuses so commonly af-

fected in orbital complications that confirmation by X ray was not considered necessary. The orbital cellulitis is considered by Babbitt as a secondary manifestation of infection—a syndrome rather than an entity. The cases with early external orbital manifestations are thought by Barwich to run a more benign course than those without external symptoms.

Approximately 75 per cent of orbital infections were secondary to disease of the nasal accessory sinuses, particularly the ethmoids, in a series of 60 cases reported by Porter. Eighty-two per cent of these were in children.

Fig. 5. Child, 3 weeks of age, showing a brawny swelling of the left side of the face. The eyelids are reddened, edematous and almost closed. The edema extended beyond the outer canthus to the temporal area and to the cheek, where the induration was also brawny in character.

Fig. 6. Frontal plane section in the region of the deciduous molar and the respiratory portion of the nose. *A* showing the breaking down of the mucosa below the inferior turbinate as though it had contained an abscess. *B* roof of the mouth in the region of the hard palate and the area occupied by corpus adiposum buccae (Bichat). *C* between the masseter and external surface of the buccinator muscles. The antrum of Highmore, *D* is filled with pus. The bony trabeculae surrounding the antrum are seen to be in considerable confusion, not adhering to the regular arrangement of the normal lamellar structure. The inferior turbinate, *E*, contains a well-walled off abscess cavity. The large fistula leading down into the mouth, *F*, is shown but in this section it appears to be connected merely with the abscess cavity in the cheek.

and of this number 7 per cent were directly due to abscessed teeth, 7 per cent to trauma, and the rest attributed to miscellaneous causes. There was a mortality of 5 per cent in this series all of the deaths occurring among children under 2 years of age.

PATHOGENESIS

The relationship of osteomyelitis to diseases of the antrum invading the anterior portion of the cavernous sinus through the ophthalmic veins is discussed by Eagleton. He believes that when the infective process originates in the teeth, it may occasion an acute osteomyelitis of the superior maxilla with involvement of the antrum; this rapidly perforates into the orbit and extends to the cavernous sinus. In these cases the infection travels not by continuity of tissue suppuration, but by retrograde thrombosis, which later is the cause of the nutritional death (gangrene with sequestration) of the osseous parts. Ballenger (3) likewise believes that acute osteomyelitis of the superior maxilla may be secondary to

buccal infection the involvement following an infection of the dental sac. The inference in such cases is that the infection originated in the tooth, from which a retrograde thrombophlebitis ascended causing not only nutritional death of tissue with consequent bony necrosis of antrum and ethmoids but also orbital abscess and finally involvement of the cavernous sinus.

An associated acute osteomyelitis is the result of the venous infection—not the cause of it. Drainage of the associated orbital abscesses cannot possibly control the disease since the infection has already invaded the cavernous sinus itself. The literature shows how invariably futile drainage operations have been performed on the orbit, the ethmoids, and maxillary antrum—futile because such drainage does not attack the thrombophlebitis itself. If these cases were diagnosed early it is possible that operation upon the thrombophlebitic veins would offer a fair prospect of recovery.

The clinical pictures of osteomyelitis of the maxilla in nurslings and infants have been variously described and many factors have been named as causes. The disease may set in during the first week or up to the ninth month of the infant's life; the greatest incidence is during the first 3 weeks after birth. Pathological manifestations of redness, swelling, purulent discharge, necrosis and sequestration may be present on any or all of the surfaces of the maxilla (orbital, nasal, facial, and palatal).

Many cases of osteomyelitis of the jaw in infants are now on record and the subject has been extensively reviewed a number of times within recent years. It is unnecessary to consider in detail all of the various opinions that have been held for the pathogenesis of this disease. In early medical literature (12) cases of this type were presented as curiosities and were published as records of the early age at which empyema of the antrum may occur rather than as contributions to the pathogenesis of the disease. In 1904 Kelly called attention to Schmiegelow's paper which had appeared 8 years before in which the clinical manifestations were attributed to an acute osteomyelitis of the maxilla. Kelly collected 17

Fig. 7 A vertical section in region of first permanent molar. The respiratory portion of the nose *A* with a break in the mucosa under the inferior turbinate indicating the rupture of an abscess. The palatal portion of the mouth indicates that a fistula has broken through the lower part of the maxillary sinus, *C* and the tract, *E* couring downward one part extending outward to a large abscess in the cheek, *D* and the other progresses downward into the oral cavity *B*. The facial wall of the sinus is completely destroyed and the presence of bone spicules is found. The zygomatic wall of the antrum as well as the root of the zygoma, *F* has been destroyed.

Fig. 8 Frontal section through first permanent molar. *A* The facial wall of the maxillary sinus is completely destroyed and a large fistulous tract containing spicules of bone, leading into the abscess in the fat pad of the cheek *B* and also finger-like projections reaching down into the tooth germ. (This photomicrograph is reversed but still concerns the same left side.)

cases including his own and concurred with the views of Schmiegelow. Since that time many theories have been advanced as to the cause of the osteomyelitis. The clinical pictures of all the cases on record are strikingly uniform although the points of entry and method of spread of the invading organism are still matters of controversy. A résumé of the various views that have been held is presented in the recent papers of Bass and Wilensky. Few of the cases reported have been studied histologically and it has been difficult to determine accurately the mechanism of the disease complex solely by clinical study. The patients are too often seen after the pathological condition is well established and as a consequence the primary seat of the process can only be inferred. Deduction by inference is the favorite method of clinicians in the reports which appear in the literature. We ourselves have never felt certain of the pathogenesis in the cases of ours that have recovered (11).

We have attempted to reconstruct pathogenic processes from clinical and histological evidence obtained by preparing serial sections of the head of an infant who succumbed to

an osteomyelitis of the maxilla (Fig 16). It appears that many possibilities are present following a nasal infection. Dogmatic statements have been made by proponents of each mode of invasion to account for the osteomyelitic process. Swoboda and Zarfl favor the theory of inflammation of the toothbuds in the course of sepsis of the newborn. This hypothesis does not fit in with the clinical history or the pathology in the majority of the cases reported in the literature. In his most recent publication on the subject Zarfl discusses the process as a necrotizing inflammation of the deciduous teeth. After an exhaustive histological study, he points out that the purulent inflammation does not begin in the tooth anlage itself but in the surrounding tissue and that involvement of the tooth anlage is secondary. On the basis of clinical and histological findings he divided his cases into two types (1) phlegmonous and (2) osteomyelitic, according to whether the soft parts or the bone were primarily involved. He presents differences in the clinical course that correlate with the underlying pathological picture. The final cause of the disease is the entrance of organisms into the soft parts or bone marrow of the jaw. The infection spreads from an inflammatory focus in the region of the jaw or from a distant focus. The cases Zarfl grouped under the phlegmonous type had circumscribed foci (erysipelas

Fig. 9. Section through the posterior choana, 1 showing the large abscess which has extended into the pterygoid fossa, B. There are two smaller abscesses in the region of the maxillary division of the fifth nerve C and a broken-down area immediately below the lateral wall of the nasal cavity.

of the face and stomatitis) the infective process extending to the jaw by way of the lymph channels. In the osteomyelitic type there was a spread through the blood stream from a distant focus such as would result from a furuncle.

According to Wilensky osteomyelitis of the maxilla differs in no way from osteomyelitis in general. The localization in the jaws in nurslings is due to such traumatic factors as those incident to childbirth, cleansing of the mouth, etc. The position of the thrombophlebitis governs the site of the necrotic process. It is Wilensky's belief that the local clinical manifestations in the maxilla are determined by the dominating position of the thrombophlebitis in the vascular channels supplying the jaws.

From careful evaluation of the case reports and data on the subject of osteomyelitis of the maxilla in infants it appears that the portal of entry and the method of spread of the primary infection may be variable. The fact that the entire tooth germ is sometimes exfoliated through the draining sinuses does not mean that the tooth anlagen were the original sites of the pathology or that they are especially liable to such involvement. It does not mean that the structures supporting them have been destroyed. In our case

despite the marked necrosis the tooth pulps withstood the destruction remarkably well.

The phase brought out in the study of this case is that nasal infection and sinusitis must be considered as a possible primary cause in osteomyelitis of the maxilla in infants. It has been suggested through the clinical reports in the literature that such etiological factors are frequently present but the fact that the sinuses are incompletely developed in infancy has obscured their significance. The maxillary sinuses and ethmoidal cells are always sufficiently advanced in their development at birth to be of clinical importance and the microscopical studies in the present case makes their importance fully evident. It would seem therefore that nasal infection and sinusitis should receive more serious consideration when the pathogenesis of osteomyelitis of the maxilla in infants is studied.

REPORT OF CASE

Osteomyelitis of the maxilla in an infant following a purulent rhinitis producing an ascending and descending abscess formation and a cavernous sinus thrombosis.

R. B. a white male infant, 3 weeks of age, was admitted to the Research and Educational Hospital. The mother stated that 9 days prior to admission, the infant had a thick, yellow nasal discharge. The infant was restless and refused to nurse. Fever was not present at this time. Two days later the nasal discharge became thin and mucoid in character and coincident with this the left eye became reddened and a swelling appeared on the upper eyelid. In the next 24 hours the lower eyelid became swollen. Forty-eight hours later the child was taken to a doctor who found a point of swelling on the left upper gum margin. The next day there was a spontaneous discharge of thick bloody purulent material from the left nostril. This was followed by a progressive decrease in swelling about the eyelids. The day before admittance the infant developed several small fluctuant areas on the left cheek near the outer canthus of the left eye and the lids again became edematous. Because of this the patient was brought to the hospital and admitted to the Pediatric Service. The mother believes that the infant has been without fever throughout the entire course of the illness. The patient was the second child of healthy parents. The mother had a normal, spontaneous delivery. The immediate neonatal history was normal and the patient did well until the time of the present illness.

Physical examination. The patient was a fairly well nourished infant. He did not appear acutely ill or toxic but was restless and irritable. No eruptions or lesions were present on the surface of the

body. Positive physical findings were confined to the head. The left side of the face was prominent. The left eyelid was reddened, oedematous and almost closed. The oedema of the eyelids extended beyond the outer canthus of the left eye almost to the temporal region. The left cheek and mandible were swollen and soft. The overlying skin had a faint purplish red color (Fig. 5). A scant amount of seropurulent material drained from the inner canthus of the left eye. The same type of discharge exuded from the left nostril and reappeared rapidly when wiped away. Pressure over the left maxilla increased the discharge from the left nostril. Upon rhinoscopic examination the material was seen to originate from below the inferior turbinate. The right nostril was clear. The left alveolar margin was swollen and boggy and a fistulous opening was present in the region of the first molar tooth. A thick yellow discharge drained from this area and was increased in quantity by pressure over the left maxilla. The pharynx was diffusely hyperemic throughout. The entire group of cervical lymph nodes on the left side was enlarged and firm to touch.

The urine was negative. Examination of the blood showed haemoglobin 68 per cent (Newcomer) red blood cells, 2,970,000 white blood cells, 13,650. The differential blood count revealed 49 per cent polymorphonuclears, 47 per cent lymphocytes, 3.5 per cent monocytes, and 0.5 per cent eosinophiles. Culture of the discharge from the left side of the nose eye and the alveolar fistula revealed *Staphylococcus aureus*.

The child's temperature on entrance was 99 degrees F but rose progressively in 4 days to 103 degrees F. Coincident with this rise there was an increase in the swelling and fluctuation of the areas described. A few fistulae developed on the left side of the face just lateral to the outer canthus of the left eye. The cervical swelling increased extending upwards to the zygoma. The patient failed to respond to supportive measures and died 6 days after entrance.

Postmortem examination. A terminal bronchopneumonia was revealed as the cause of death. A special histological study of the head was begun by Dr. Blayney of our Dental Department and collaborated in by Dr. Poncher and myself (13).

Microscopical report. The histological sections disclosed microscopical changes which were entirely in accordance with the clinical symptoms. The frontal section through the plane of the deciduous molar (Fig. 6) shows an old extensive osteomyelitic process of the inferior turbinal bone and also an involvement of the maxillary sinus which is much more recent. The lower border of the maxillary sinus presents a dehiscence from which a fistulous tract leads downward and then divides, one tract extending outward to a large abscess in the cheek and the other portion progressing downward into the oral cavity (Fig. 7).

A careful dental study of these histological preparations was made with particular reference to the

Fig. 10. Vertical section through the central region of the soft palate and the body of the lesser wing of the sphenoid. On the lateral wall of the epipharynx A is a cartilaginous projection which is the lamina medialis of the eustachian tube with the abscess encroaching upon it. The mandibular nerve is in close proximity to the abscess. The abscess, B, is located between the tensor and levator veli palatini muscles, from above and the buccinator belly of the superior pharyngeal constrictor below C. In the destruction of the zygomatic root the process extended into the pterygomaxillary fossa.

soft tissues covering the tips of the enamel cusps and incisal edges of the deciduous teeth. Each dental anlage showed a sufficient pad of soft tissue between the oral epithelium and the tooth crown precluding the possibility of any postnatal laceration or exposure of the tooth germ. It is quite evident that the involvement of the inferior turbinate is considerably older than that seen in the other regions of either the maxilla or mandible. These findings strongly suggest that the original infection was in the nasal cavity.

The frontal section through the plane of the first permanent molar region, reveals that the facial wall of the sinus is completely destroyed. A large fistulous tract containing apicules of exfoliated bone is seen to lead into the abscesses of the cheek and a finger like projection reaches downward, external to the tooth germ (Fig. 8). The zygomatic process of the antrum is seen to be destroyed with an extension of the phlegmonous process into the pterygomaxillary fossa. There are two smaller abscesses in the immediate vicinity of the maxillary division of the fifth nerve and also one small abscess beneath the periosteum of the lateral wall of the nasal cavity (Fig. 9). Sections were studied through the various planes from this point posteriorly such as the soft palate, the lesser wing of the sphenoid, the uvula, the body of the sphenoid and the sphenoidal fissure, and the greater wing of the sphenoid (Fig. 10). In the pterygoid fossa there is a small abscess and there are septic thrombi in a number of the adjacent veins. In a section anterior to the posterior wall of the pharynx, including the body of the

Fig. 1. Section at the level of the uvula, the body of the sphenoid, the sphenoidal fissure and the greater wing of the sphenoid. The posterior pharynx, A and pharyngeal space including the tonsil, B are normal but the abscess, C in the muscle planes, shows much destruction of surrounding parts and septic thrombi in the nearby veins. The abscess is located in close proximity to the eustachian tube.

Fig. 2. Section in a plane just anterior to the distal wall of the pharynx, A and including a portion of the greater wing of the sphenoid, the basilar process, B and the abscess in the parapharyngeal area. The cavernous sinus area, D, including the internal carotid artery with the associated nerve trunks and ganglia (trigeminal [ophthalmic, superior and inferior maxillary (mandibular) branches], abducens, oculomotorius and trochlearis).

sphenoid and the basilar process, the cavernous sinus, the internal carotid artery with the associated nerve trunks and ganglia and a portion of the greater wing of the sphenoid are anatomically recognized (Fig. 13). There are several septic thrombi in the cavernous sinus (Figs. 13 and 14). The extension from the antrum through the maxilla was not limited to the distal direction but involved also the structure immediately above the deciduous central incisor and cuspid; the soft tissue between the oral cavity and the tooth crown was normal and unbroken (Fig. 15).

The study of the mandibular sections by Dr. Blayney disclosed an osteomyelitic process extending forward from the mandibular foramen to the region of the deciduous cuspid (Fig. 15, A). The degree of phlegmonous reaction and the amount of tissue destruction was much more pronounced in the maxilla than in the mandible. The mandible was separated from the maxilla at the time of autopsy so that it is impossible to trace the direct extension of the aforementioned infectious process. However, in a section through the mandibular foramen the abscess may be seen to enter the body of the mandible along with the mandibular nerve and vessels. Having seen that the syphagmatic process of the maxillary bone had been destroyed and that the contents of the maxillary sinus had entered the pterygomaxillary fossa, it is readily understood in what manner the extension could take place along the planes of the buccal fascia, the pterygoid muscles, the sheaths of the third division of the fifth nerve and the inferior dental artery, thereby entering finally the lower jaw through the mandibular foramen (Fig. 10).

In a section through the first permanent molar region, a large abscess is found immediately beneath the dental pulp, in close proximity to the mandibular nerve (Fig. 15, B). Inferior to this, the major portion of the original mandibular bone is involved in an osteomyelitic process. The body of the mandible is completely surrounded by a formation of new bone, the trabeculae of which are arranged at right angles to the surface. This arrangement of the trabeculae is not present on the normal side and by its form suggests an effort on the part of nature to withstand the effects of internal pressure. Studies of the deciduous molar teeth reveal a large area of destruction, extension of this process along the lateral wall of the tooth and complete disorganization of the enamel organ on the occlusal surface. The overlying soft tissue despite these pathological alterations, is intact, thereby discounting any dental focus as a pathogenic factor.

Throughout the entire mandibular series, we are unable to find a trace of the inferior dental artery from a point posterior to the cuspid region. This fact seems to substantiate the statement that the infection entered the lower jaw by extension along the vessel sheath, ultimately destroying it, and that the involvement of the lower jaw was not the result of a thrombophlebitis. In the anterior region of the mandible the structures are found to be normal in appearance and arrangement.

Summary of the clinical and histological findings. The clinical course of the patient becomes coherent after close scrutiny of the serial sections of the entire head. There is incontestable evidence that the site of origin of the infection was in the inferior turbinate. Following a purulent rhinitis and sinusitis,

Fig. 13. High magnification through the internal carotid artery which is filled with septic thrombi.

Fig. 14. Area of cavernous sinus showing veins thrombosed and containing septic thrombi.

the infant developed a periosteitis of the maxillary and ethmoid sinuses and periorbital cellulitis which later broke down (Fig. 5). From the suppurative process in the maxillary sinus and ethmoidal labyrinth septic thrombi invaded the venous channels producing a cavernous sinus thrombosis (Figs. 12, 13, 14). From the original site, the process extended to the maxillary sinus, producing a fulminating infection. The exudate in the maxillary sinus, by denuding the bone, caused a necrosis which gave rise to a fistulous tract at the floor of the sinus and broke through into the roof of the mouth (Figs. 6 and 7). The facial surface of the maxillary sinus was eroded by the carious process, thereby causing extension by continuity into the zygomatic arch and the soft tissues of the cheek (Figs. 7 and 8). The pterygoid fossa then became included in the extension from the zygoma (Figs. 9 and 10) and, by way of the fascial planes traveling along the pterygoid and buccinator muscles, the mandibular foramen became involved. The invasion of the foramen was by way of the nerve and vessel sheaths, and in the process one nerve was found to remain intact but the vessels were completely destroyed (Fig. 15). The parapharyngeal space contained a broken down abscess (Fig. 11).

The changes in the interior of the nose were most interesting. The osseous portion of the inferior turbinate was replaced by a necrotic mass. This is seen to be almost encysted, hence it would seem to be an older process (Fig. 6) than those which resulted from this infection. The epithelium of the turbinate is almost devoid of cilia although the mucosa is everywhere intact except in the inferior

meatus where it has been destroyed (Fig. 7). This destruction in the inferior turbinate represented the oldest change, the fistula at the floor of the maxillary sinus and the organized thrombus in the cavernous sinus were next in sequence.

TREATMENT

Neither experience nor literature seem to solve the problem of therapy in these cases. Extremes of conservatism and radicalism are represented, with a fortunate tendency to the former. A typical experience is that of Ballenger (2) who had 8 spontaneous recoveries out of 11 cases with no drainage other than that provided by the natural nasal orifices. Two of the cases drained by a spontaneous rupture through the orbit, one through the inner and another through the outer canthus of the eye. The 2 other cases required surgical interference, one an ethmoidal and the other an ethmoidal and orbital drainage. All of these cases recovered. Such an experience is not unusual.

Whether packs externally applied should be hot or cold is a matter of controversy; there being enthusiastic proponents for each form of therapy. Intranasal shrinkage and mild suction or irrigation are valuable. Procedures such as infraction of a turbinate, probing or irrigation of sinuses have not met with universal acceptance. The opinion often voiced is that these cases, representing as they do a fulminant type of pathological process, offer a

Fig. 5. A study of the mandibular series. A Shows the area immediately above the deciduous central incisor and cuspid involved. However the soft tissue between the oral cavity and tooth crowns is normal and unbroken. B Section through the first permanent molar region. There is an abscess immediately beneath the dental pulp and in close proximity to the mandibular nerve. The major portion of the bone surrounding this area is in old in the osteomyelitic process. The body of the mandible is completely surrounded by new bone with trabeculae arranged at right angles to the surface. C The section through the mandibular foramen shows the abscess entering the body of the lower jaw along with the vessels and the nerve, which really constitutes the manner in which infection was carried to the mandible. D The anterior region of the mandible shows a more active osteomyelitic process with sequestration and abscess formation.

better prognosis with a 'hands off' policy. Those who have voiced this ultra-conservative attitude have probably experienced in their own hands or those of their colleagues unfortunate sequelae of sepsis, osteomyelitis, meningitis and dural sinus thrombosis. They lean therefore toward the opinion that any manipulation in the nose may bring on dire consequences having no proof that the cases might not have gone on to such complications without these procedures.

In discussing the intranasal cases producing orbital symptoms and abscess, Faulkner advocates external evacuation of the abscess and exenteration of the ethmoids. Babbitt comments on the similarity in the symptoms of orbital cellulitis and cavernous sinus throm-

bosis; he believes that the percentage of recoveries under radical procedures and the serious prognosis without interference justifies initial nasal sinus surgery even in cases of doubt.

The treatment of orbital cellulitis and abscess varies with the severity of the symptoms according to Hawkins, who treats cases of pure edema intranasally. He quotes Logan Turner who was able to cure 14 of his 58 cases in this manner. Children with ethmoid suppuration and exophthalmos responded to shrinkage suction or irrigation in 24 to 48 hours, in Hawkins cases. He further advises that adults may respond to simple irrigation but according to him may require some type of operative procedure—intranasal, external,

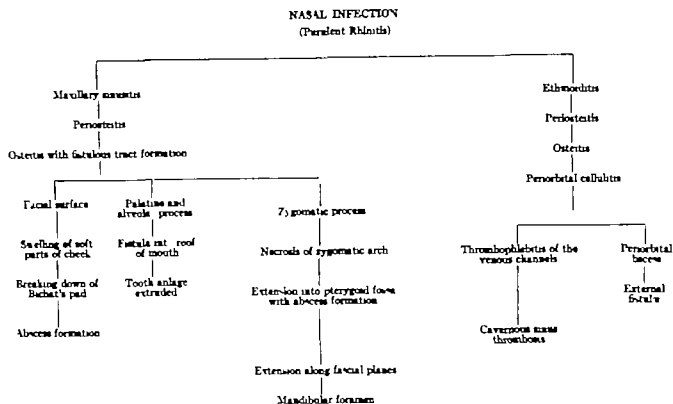

Fig. 16 Graphic representation of the method of spread from a primary focus in the nose to structures of the surrounding portions of the head. It is seen that this chronological representation follows very closely the comparative study of the historical sequence and the study of the histological series. Represented are possibly all the various routes by which a nasal infection may spread to the adjacent parts

combined or drainage of an orbital abscess. Whatever the type of operation it should be sufficiently radical to insure adequate drainage both of the infected sinus and the orbital pus. Such a radical attack should be carried out immediately when a cavernous sinus thrombosis manifests itself.

An expectant conservative attitude is adopted by Porter if there is a simple oedema of the lids (which he terms the first stage). This consists of shrinking the nasal mucosa, warm saline irrigations and cold compresses externally. If after 24 to 48 hours there is no improvement or if the condition has progressed he advocates for children who have cloudy ethmoids and antra a removal of the anterior ends of the middle turbinate opening into the ethmoid labyrinth and frequently uses intranasal antrotomy. In the adult the radical antrum operation is performed instead of the intranasal. If there is oedema of the lids and exophthalmos with limitation of motion (he terms this the second stage), an even more immediate and radical intervention is advised, consisting of an external ethmoid

exenteration and possibly removal of the floor of the frontal sinus and a sublabial approach to the antrum if it is involved.

On the basis of clinical reports it is difficult to arrive at an adequate evaluation of the therapy in these fulminant sinus infections. We can say definitely that conservative measures will suffice in the majority of cases, where the bacterial invasion is not virulent and its nidus is within natural cavities that may be readily drained. Such foci may be drained by shrinkage medication, suction or irrigation. With areas that are not so accessible a surgical approach becomes necessary. As Porter has shown, surgery is obviously indicated when the process is not responding to the expectant treatment and drainage is not established. Intranasal surgery has always been shunned in the presence of an acute infection and statistics seem to indicate that surgical intervention in fulminant sinus infections is attended by an appalling morbidity and mortality. Such statistics are logical only if we know at what stage of the infection drainage was attempted and the character of the procedure

(especially the incident trauma) External procedures rather than intranasal operations have been advised because of a possible spread to the meninges. We feel that here again we should choose the route nearest to the area which we desired to drain and—more important still—should as far as possible avoid operative trauma. We have frequently found it best to advise procedures in accordance with the ability of the surgeon.

CONCLUSIONS

An interesting histological survey directed toward study of the pathogenesis of osteomyelitis of the maxilla in an infant and of the means of extension and complication reveals a great number of diverse basic factors in cases clinically similar to each other. It is evident from a study of the literature that the portal of entry and method of extension may be variable. Dogmatic statements have been made by proponents of each mode of invasion but a careful study of our case has shown that the various modes of extension may all be involved in such processes. Evidence is presented to show conclusively that nasal infection and sinusitis may play an important rôle in the pathogenesis of such a process even in early life.

Very few of the cases recorded in the literature have had serial histological studies, and because it is difficult to determine the disease complex solely by clinical means, dogmatic and erroneous conclusions have been forced upon the rhinologist. The patients are often first seen after some time has elapsed so that the primary process is declared by inference only. The present study offers a logical explanation of many earlier unexplained cases.

We advise an expectant conservative attitude in the early stages of the disease when oedema of the lids is present. If the process does not show a tendency to regress and if symptoms become more marked surgical intervention must be contemplated.

The surgical approach can be intranasal or extranasal, the route determined depending upon the proximity to the focus to be drained and the chances of avoiding trauma. The

choice of procedure depends chiefly upon the technical skill of the surgeon.

In the case reported probably no therapy conservative or radical, could have halted the extensions of the bacterial invader or saved the life of the patient. Past experiences would indicate that palliative medication has its distinct merits in the treatment of the majority of cases. Radical interference undertaken at the proper time should give a good prognosis. Of the operative procedures surgery for drainage appears most advantageous.

NORMAL HUMAN OVUM IN THE PRIMITIVE STREAK STAGE (APPROXIMATELY EIGHTEEN AND ONE-HALF DAYS)¹

HAROLD O. JONES, M.D., F.A.C.S. AND JOHN I. BREWER, M.D. CHICAGO, ILLINOIS

COMPARATIVELY few young human ova normal and anatomically complete have been described. The ovum² to be reported here seems to fulfill these requirements. In addition, an exact sex history has been obtained from the husband and wife as follows:

February 16, 1932, menstruation began.
February 22, 1932, menstruation ended.
February 26, 1932, coitus.
February 28, 1932, coitus.
March 4, 1932, coitus (evening).
March 10, 1932, entered hospital.
March 13, 1932, menstruation expected but failed to occur.
March 24, 1932, hysterectomy (morning).

The body of the uterus as removed measures 10.5 by 7.5 by 4.5 centimeters and has no pathological changes. The wall is 3 centimeters thick, 1 centimeter being endometrium. The cavity has no blood. On the posterior wall of the endometrium there is a slightly depressed hemorrhagic tissue 1 millimeter in diameter. Centered 1 millimeter directly beneath this is the blastocyst. The external measurements of the unfixed chorionic vesicle are 8 by 7 by 4 millimeters. The internal measurements (chorionic cavity) are 6 by 5 by 2.5 millimeters. The yolk sac is 1 millimeter in diameter before fixation. The amniotic cavity measured in the section is 0.66 by 0.816 by 0.20 millimeters in its greatest dimensions. The caliper measurements of the embryonic disc made on the model at 200 diameters are 115.9 millimeters long by 147.5 millimeters wide. The primitive groove similarly measured is 40.9 millimeters long. The length of the primitive streak including Hensen's node is 87.5 millimeters. Reduced to actual size the length of the disc is 0.58 millimeters, the width 0.74 millimeters, primitive groove 0.205 millimeters and the primitive streak including Hensen's node 0.438 millimeters.

These facts and those to follow support the conclusion that this ovum is normal and complete. The normal uterus was removed for the purpose of sterilization. The imbedded ovum was implanted at the usual site on the posterior wall of the uterus. The size and stage of development of the ovum were consistent with the menstrual and coital histories. Invasion of the maternal tissue by fetal elements was in active progress. The fundamental relationships of the embryonic plate, yolk sac, amnion, chorion, villi and endometrium were normal and agreed with those described by Bryce-Teacher, Frassa, Eternod and others which are accepted generally as normal. The cells of the embryonic plate were in active mitotic division. The Langhans' cells and the cytotrophoblast were multiplying rapidly by mitotic division. There was no cellular degeneration of the villi. Anchoring villi were few and were loosely attached.

The ovum and the embryonic anlage were anatomically complete and were sectioned and arranged serially. The entire unfixed blastocyst tissue together with a small amount of the surrounding endometrium was divided into four portions and placed in fixing solutions within 10 minutes after the maternal blood supply had been clamped. The block of tissue containing the embryonic anlage was fixed in formalin Zenker's solution, and the 3 others were placed respectively in Regaud's solution, 10 per cent neutral formalin, and formal Zenker's solution with subsequent osmic acid fixation. All the tissues were imbedded in paraffin. The block containing the embryonic structures was cut serially at 10 microns, and the sections were stained with hematoxylin and eosin. All other blocks were cut serially at 5 to 6 microns.

The stains used were acid fuchsin, methyl green, acid fuchsin Mallory III, phosphotungstic acid hematoxylin, osmic acid counterstained with methyl green, copper chrome hematoxylin, iron alum hematoxylin, scarlet

¹A comprehensive description of the embryo will be published later.

red, Best's carmine Bielschowsky silver technique Mayer's muchematein Bismark brown and haematoxylin and eosin

ESTIMATION OF AGE

The coital history presents crucial evidence for determining the age of our ovum. Recent evidence indicates that ovulation usually occurs near the middle of the menstrual cycle (Allen et al). Accordingly the last ovulation in our patient occurred about March 3, 1932. The viability of injected spermatozoa in the human is variously stated to be from 1 to 3 days. Thus the coital relations that occurred on February 26 and 28 are too far separated from the calculated date of ovulation to be significant. The isolated and last coitus on March 4, 19½ days before operation coincides closely with the estimated date of ovulation. On this basis the maximum copulation age is 19½ days. The minimum copulation age is 14 days, since the patient was in the hospital 14 days prior to operation. Mall states that the copulation age is 24 hours longer than the actual or fertilization age. Deducting 1 day from the computed ovulation age the fertilization age of our ovum is 18½ days.

The calculated age is substantiated by comparison with other young human ova. The Grosser (Kl.) Ingalls Heuser Frass and Eternod (Vull) specimens (about 19 days) have larger measurements, the external diameter of the chorion being 10 millimeters. The Grosser and Ingalls ova have head processes, chordal canals, cloacal membranes and beginning medullary folds. The Frass and Eternod ova contain in addition neuronic canals, medullary grooves, and blood vessel formations in the body of the embryos.

The ova described by Miller Bryce Teacher I Peters Jung Verttens, and Strahl Beneke have internal chorionic measurements ranging from 0.44 millimeters to 3.8 by 2.2 by 1.2 millimeters. The measurements of the embryonic shields, while not absolutely trustworthy, vary up to 0.75 by 0.3 millimeters. The well known Miller and Bryce Teacher I ova have no definitive villi while one described by Peters has beginning villi formations. In the Jung specimen the villi evidence some branching.

In the Strahl Beneke ovum a primitive streak is present. The ages of these ova are stated by Streeter to be from 11 to 15 days and by Grosser from 12 to 18 days. (The Miller ovum is not listed in Grosser's classification. Grosser 1927.) Falkner recently described a human ovum associated with a good clinical history and estimated its age at 15 days. The villi are beginning to branch and the yolk sac is larger than the amnion.

Closely approximating the description of our ovum is that of the Mateer ovum, the age of which is placed by Streeter at 17 days. The measurements of the Mateer ovum, however, are slightly greater. The blood vessels of the villi contained primitive blood cells while in our specimen the vessels are empty.

Kindred in reporting the Goodwin ovum, calculates the age to be about 19 days. Although the given measurements are smaller than those for our ovum, the presence of the described head process indicates it to be more mature.

Our ovum with its primitive groove, allantois, blood vessel formations in the wall of the yolk sac, in the body stalk, in the chorionic membrane and in the villi with a yolk sac larger than the amnion and with branching villi falls into Group II of Streeter's classification. The internal measurements of the chorion are also within the limits given by Streeter for this Group. Since our ovum contains the earliest stage in the formation of a neuronic canal that has been described for the human, it is placed in the borderline between Groups II and III (Streeter). It is definitely less advanced than the ova of Group III (Grosser Kl.) Ingalls Heuser Frass, and Eternod Vull.

The more exact estimation of its age (18½ days), the immediate and excellent fixation, the favorable plane of section, and the completeness of the specimen make possible a precise classification of this ovum in the series of human ova.

THE VILLI

The villi vary in size and shape and cover the entire surface of the blastocyst (Fig. 1). The longest is 0.1 millimeters. Many are branched once and a few twice. Each has a central mesodermal core and a covering of

syncytium and Langhans' cells. The Langhans' cells are small, cuboidal, or oval with scant granular cytoplasm large clear nuclei and one or two nucleoli (Fig 2). Each cell has a definite membrane. Many are in mitotic division. Glycogen can be stained in these cells. The vacuolization of the cells as demonstrated by Falkner was not present. The syncytium is a finely granular protoplasmic film with nuclei distributed through it. It is spread irregularly over the surface of the Langhans' cells and stained deeply. The nuclei have a single nucleolus. Glycogen could not be demonstrated in this syncytium. Mitochondria stain as thin threads. In many places there is a brush border. The syncytium does not in this specimen completely surround and wall off the implantation cavity the picture differing in this respect from that described by other writers.

VASCULAR ANLAGE

There are blood vessels in various stages of development in the villi chorion body stalk and in portions of the wall of the yolk sac. In the villi chorion and body stalk the development is similar while in the yolk sac the formations differ and are considerably more advanced.

All the larger villi contain angioblastic strands or short tubes, while many of the smaller villi do not. In the absence of specific study and plotting there is no manifest difference in the number or degree of development of vessel formations in the villi chorion and body stalk. All stages from fine mesodermal strands to fully formed short endothelial tubes are present. The strands usually located near the center of the villi consist of groups of mesodermal cells with indistinguishable cell membranes. They are short and in serial sections have no connections with other neighboring strands or vessels. Some contain vacuoles in the central portion. Because the cell boundaries could not be discerned, it can not be stated whether the vacuoles are intracellular or extracellular. By confluence and enlargement of the vacuoles a lumen is formed surrounded by a ring of cytoplasm and flattened nuclei. These formations likewise are isolated. A few of the formations are branched.

Fig 1 Photomicrograph of a slightly oblique section of blastocyst embedded in endometrium. Section 15-2 X12

Since the vessel primordia are distributed evenly through the villi chorion, and body stalk, since the individual strands and vessels are independent of connections or communications with neighboring strands, and since the formations are equally well differentiated over the entire chorion they probably arise *in situ*. There are no cells in the lumen of the endothelial tubes in the villi, such as Streeter described for the Mateer ovum and called future blood cells. In the body stalk there is similar differentiation of mesoblastic cells into strands—some solid some with vacuoles, and some with a lumen. There is no evidence that these as yet join with the strands of the chorionic membrane. In a place at the edge of the body stalk is a single blood island formation similar to those observed in the wall of the yolk sac.

In the wall of the yolk sac, the blood vessel formations are restricted to the caudoventral

Fig. 5. Photomicrograph of a fetal wandering cell in contact with a decidual cell at the left. Stained with Best's carmalum to show glycogen. $\times 975$.

Glycogen is present in large cells scattered through the decidua at the sides and base of the blastocyst (Fig. 5). Beneke, P. Meyer, Bryce-Teacher, Peters, Strahl and Falkner describe these large cells, but make no statement concerning their glycogen content which in our material distinguishes them from maternal cells. Beneke, Meyer, Strahl and Falkner believe these cells to be of fetal origin while Bryce-Teacher suggests that they are maternal cells. Peters states he is uncertain of their origin.

Two types of fetal wandering cells are evident. In our specimen their origin can be traced definitely to the cytotrophoblast. Cells in the cell columns at the tips of the villi identical with Langhans cells increase in size, the cytoplasm concentrates about the nuclei and the acid stain is taken with avidity. The cells increase in size, the cytoplasm becomes more dense and the nuclei have one or more clefts and a single large nucleolus. The cytoplasm becomes still more dense and granular, remains concentrated about the nuclei and stains more intensely with acid dyes. In the cytoplasm mitochondria now appear stained as long thin threads and filaments. Figure 6 illustrates such a cell among its neighbors and separated from the decidua by a venous space. The mitochondria are similar in sections fixed in Regaud's solution and in formal Zenker's with subsequent osmic acid fixation for two days. In Figure 7 a wandering cell of one type is shown in the decidua adjacent to a

vessel. By comparison to a decidual cell the fetal cell is larger. It contains glycogen in this preparation and the decidual cells do not. It has mitochondria whereas the decidual cells do not. The nuclei of the decidual cells are even rounded or oval with 1, 2 or 3 small nucleoli in contrast with the cleft nuclei and single large nucleoli of the fetal wandering cells. The other type of fetal wandering cell is illustrated by Figure 5. These cells stain darkly and invade the decidua in streamer-like formations, one cell behind the other. Their shape varies during invasion. Many are elongated and tenuous as in Figure 5. Others located in maternal capillaries are spherical. Many contain glycogen and in some mitochondria stain as threads and short rods. Some have several nuclei.

SYNCYTIUM

The theory that syncytium originates from the cytotrophoblast is upheld by Peters, Streeter, Jung, Miller and others. The theory that it originates from maternal endothelial cells has been so convincingly disproved that it can safely be disregarded. In the ovum reported here the formation of the syncytium is followed from the cytotrophoblast in more detail than has previously been done.

The syncytium develops similarly to the fetal wandering cells as noted above up to the appearance of mitochondria. From here on, a variation occurs. After the formation of the large cytotrophoblastic cells with dense cytoplasm and mitochondria, two or more of the cells fuse to form a multinucleated mass or such a single cell is surrounded and taken up by an already formed syncytial mass. The staining reaction of the syncytium is similar to that of the large cytotrophoblastic cells. Mitochondria remain as thin threads in the syncytium (Fig. 8). Identical changes with the subsequent formation of syncytium take place in the Langhans cells within the confines of the villi. Since syncytium develops from the Langhans and the cytotrophoblastic cells in a similar manner it is evident that these latter two cell types are fundamentally similar and have a common origin. Many of the syncytial masses have brush borders (Fig. 9). Brush borders or prickles

Fig. 6 Camera lucida drawing of venous space in penetration zone. *a* Endometrial stromal cells, *b* endothelial lining of venous space *c* lumen of venous sinus *d* cytotrophoblast replacing endothelial wall *e* cytotrophoblastic cell with mitochondria $\times 725$

processes have been noted by Jung Greenhill Beneke Marchand and others Peters believes these irregular borders are not prickly processes but rather a frayed deposit on the surface. The masses penetrating deepest into the maternal tissue in our ovum do not have these borders and Bryce Teacher report similar findings. Numerous masses contain lipid droplets stained with both scarlet red and osmic acid (Fig. 9). In the penetration zone many syncytial masses with brush borders contain large and small vacuoles. In sections fixed and stained for lipoids these vacuolated regions do not stain. It is probable that the brush borders are associated with phagocytic activity of the cell masses as suggested by Bartelmez.

In the penetration zone *Zwischenzone* or zone of necrosis Grosser reports an abrupt transition from the trophoblast to the maternal tissue in the Kleinhaus ovum and believes the maternal tissue is not destroyed but merely pushed outward. Veit Strahl Beneke and P Meyer also note this outward displacement. Streeter states there is no destruction

or ingestion of maternal stroma cells in the Miller ovum. On the other hand Bryce and

Fig. 7 Drawing of a section containing a fetal wandering cell with mitochondria amidst maternal cells. (Stained with aniline acid fuchsin and methyl green) Camera lucida $\times 1065$

Fig. 5. Photomicrograph of a fetal wandering cell in contact with a decidual cell at the left. Stained with Best's carmalum to show glycogen. $\times 95$.

Glycogen is present in large cells scattered through the decidua at the sides and base of the blastocyst (Fig. 5). Beneke, P. Meyer, Bryce, Teacher, Peters, Strahl and Falkner describe these large cells but make no statement concerning their glycogen content which in our material distinguishes them from maternal cells. Beneke, Meyer, Strahl and Falkner believe these cells to be of fetal origin while Bryce, Teacher suggest that they are maternal cells. Peters states he is uncertain of their origin.

Two types of fetal wandering cells are evident. In our specimen their origin can be traced definitely to the cytotrophoblast. Cells in the cell columns at the tips of the villi identical with Langhans' cells increase in size, the cytoplasm concentrates about the nuclei and the acid stain is taken with avidity. The cells increase in size, the cytoplasm becomes more dense and the nuclei have one or more clefts and a single large nucleolus. The cytoplasm becomes still more dense and granular, remains concentrated about the nuclei and stains more intensely with acid dyes. In the cytoplasm mitochondria now appear stained as long thin threads and filaments. Figure 6 illustrates such a cell among its neighbors and separated from the decidua by a venous space. The mitochondria are similar in sections fixed in Regaud's solution and in formal Zenker's with subsequent osmic acid fixation for two days. In Figure 7 a wandering cell of one type is shown in the decidua adjacent to a

vessel. By comparison to a decidual cell, the fetal cell is larger. It contains glycogen in this preparation and the decidual cells do not. It has mitochondria whereas the decidual cells do not. The nuclei of the decidual cells are even rounded or oval with 1, 2 or 3 small nucleoli in contrast with the cleft nuclei and single large nucleoli of the fetal wandering cells. The other type of fetal wandering cell is illustrated by Figure 5. These cells stain darkly and invade the decidua in streamer-like formations, one cell behind the other. Their shape varies during invasion. Many are elongated and tenuous as in Figure 3. Others located in maternal capillaries are spherical. Many contain glycogen and in some mitochondria stain as threads and short rods. Some have several nuclei.

SYNCYTIUM

The theory that syncytium originates from the cytotrophoblast is upheld by Peters, Streeter, Jung, Miller and others. The theory that it originates from maternal endothelial cells has been so convincingly disproved that it can safely be disregarded. In the ovum reported here the formation of the syncytium is followed from the cytotrophoblast in more detail than has previously been done.

The syncytium develops similarly to the fetal wandering cells as noted above up to the appearance of mitochondria. From here on a variation occurs. After the formation of the large cytotrophoblastic cells with dense cytoplasm and mitochondria, two or more of the cells fuse to form a multinucleated mass, or such a single cell is surrounded and taken up by an already formed syncytial mass. The staining reaction of the syncytium is similar to that of the large cytotrophoblastic cells. Mitochondria remain as thin threads in the syncytium (Fig. 8). Identical changes with the subsequent formation of syncytium take place in the Langhans' cells within the confines of the villi. Since syncytium develops from the Langhans and the cytotrophoblastic cells in a similar manner it is evident that these latter two cell types are fundamentally similar and have a common origin. Many of the syncytial masses have brush borders (Fig. 9). Brush borders or pickle

noid In some places formation of fibrinoid from degenerating syncytium is noted Small amounts are evident, scattered through the advancing cytotrophoblast from which it apparently originates In other places, the origin is undoubtedly in degenerating maternal cells at the boundary zone In contrast to the description by Bryce and Teacher and Jung, in which the fibrinoid is arranged in a layer completely around the ova, it is found only in occasional places in our ovum, while in the Peters' ovum it is entirely wanting When it occurs it is located at the junction of the decidua and the cytotrophoblast which it separates sharply The layer is usually thin In Greenhill's specimen, fibrinoid was being engulfed by the syncytium

Fibrin occurs mainly in the formation of thrombi In many places a capillary opens into the intervillous space, one endothelial wall is lost and the other continues along the edge of the normal decidua Adherent for a considerable distance along this remaining capillary wall is a laminated thrombus made of fibrin, and white and red blood cells Fibrin is located only in the vessels in the penetration zone

SUMMARY

- 1 A normal and anatomically complete human ovum, age 18½ days is described (Fig 1)
- 2 The tissues were fixed in various solutions within 10 minutes after the clamping of the maternal blood supply
- 3 An accurate and valuable clinical history is given.
- 4 The embryonic disc is slightly oval and contains
 - a. The earliest stage in formation of a neurenteric canal so far described for the human,
 - b. A primitive streak and groove (Figure 1)
 - c. A Hensen's node,
 - d. A cloacal membrane,
 - e. An allantois.
- 5 The villi surround the entire blastocyst (Fig 1) Some are branched (Fig 1) There are a few anchoring villi (Fig 2)
- 6 Blood vessel formations arise *in situ* They are identified in the villi, chorionic mem-

brane, body stalk, and yolk sac wall (Fig 3) There are primitive blood cells in the vessel formations of the yolk sac (Fig 3)

7 The cytotrophoblast is of fetal origin (Fig 2) and contains glycogen In it there is no reticular framework in sections stained by Bielschowsky's silver method (Fig 4)

8 Two types of fetal wandering cells develop from the cytotrophoblast. Both contain glycogen and mitochondria The latter are stained as thin rods and filaments (Figs 5 and 7)

9 The syncytium originates from the cytotrophoblast and Langhans' cells in a similar manner (Figs. 2 and 8) The mitochondria stain as thin threads (Fig 8) Many syncytial masses have brush borders (Fig 9)

10 In the penetration zone there is degeneration of maternal tissue (Fig 4) as well as an outward pressure exerted by the growing blastocyst (Fig 1)

11 The slight leucocytic infiltration in the implantation site is limited principally to the decidua capsularis

12 Fibrinoid is formed from both fetal and maternal tissues in the penetration zone

We wish to express our appreciation for the valuable suggestions and aid given by Dr George W. Bartelmez.

STUDIES ON ABSORPTION AND EXCRETION IN SEGMENTS OF THE COLON OF MAN¹

FILLMORE S. CURRY, M.D., ROCHESTER, MINNESOTA
Fellow in Surgery The Mayo Foundation

J. ARNOLD BARGEN, M.D., ROCHESTER, MINNESOTA
Division of Medicine The Mayo Clinic

MUCH conflicting experimental evidence exists concerning the absorption of substances other than water by the large intestine. While we were working with a large group of colostomized patients on the combined intestinal service of the Mayo Clinic it occurred to us that they presented conditions ideally suited to the elimination of the usual fallacies inherent in investigations of colonic absorption, and that, without inconvenience or danger to patients observations could be made which would be of benefit to all patients. The particular advantages offered by colostomized patients were as follows: (1) The omnivorous colon of man could be studied, rather than the colons of strictly carnivorous or strictly herbivorous animals. (2) The divided colon would prevent error due to regurgitation of the clyma into the absorbing ileum. (3) Short distal segments could be thoroughly evacuated thereby eliminating any errors due to failure to recover unabsorbed fractions. (4) Thorough cleansing of the easily accessible, short, distal segment would prevent bacterial fermentation in experiments with carbohydrates.

Test substances were chosen with a view to obtaining additional evidence of absorption other than disappearance from the colonic lumen as well as for utility of these substances otherwise. For these purposes a number of observations were made, using methylene blue, atropine, glucose, sucrose and arsenic. Experiments were also performed to determine whether some of these substances, orally or intravenously introduced would be excreted by the colonic segments.

METHOD

The distal colonic segment was thoroughly cleansed by irrigations with warm tap water rubber catheters were used, as is illustrated in Figure 1. That this cleansing process was

effectual is evidenced by the fact that the content of a segment, removed after cleansing, failed to cause any loss of fermentation, when incubated for 4 hours at 37 degrees C with 5 grams of glucose.

Following the process of cleansing, the substance to be tested was instilled in solution through the rubber catheter, and left in the segment for the duration of the observation as determined by its nature. At the end of this time, the unabsorbed fraction was removed by irrigation, and its quantity determined. That the unabsorbed fraction could effectually be removed in this manner was demonstrated by instilling 30 milligrams of arsenic as neo-arsphenamine, in solution, and immediately removing it by irrigation with 1,000 cubic centimeters of water. Analysis of this returned fluid by the Osterberg modification of the Gutzeit method resulted in recovery of 97 per cent of the instilled arsenic.

ABSORPTION

Results with methylene blue are given in Table I, those with atropine, in Table II, and those with glucose in Table III.

To determine metabolic factors during the disappearance of glucose from the colonic segments, observations were made on 3 individuals, free of diabetes, on whom colostomy had been performed at the level of the sigmoid, on one individual, who had diabetes graded 3, on whom colostomy had been performed at the level of the sigmoid, and on one individual who had undergone obstructive resection at the level of the sigmoid and who had questionable latent diabetes. Under basal conditions estimations of the respiratory quotient and heat production, in calories per square meter per hour, were made by the gasometer method (2), and the values for blood sugar were determined by the Folin Wu method. Following introduction of 30 or 50 grams of glucose into

Abstract of thesis submitted by Dr. Curry to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science in Surgery. Work done in the Divisions of Medicine and Surgery, The Mayo Clinic.

Fig 1. Anatomical condition after double barrel or loop colostomy and method of using catheters.

the distal colonic segment, the same determinations were made at hourly intervals for 3 hours, with an additional determination of blood sugar at the first half hour. Table IV shows that in each case mentioned in the foregoing there was an increase in heat production, and in 3 instances there was an increase in respiratory quotient above the basal levels at some point during the disappearance of 9.42 to 48.75 grams of glucose from the distal colonic segments.

Among individuals whose carbohydrate metabolism was not impaired, the values for blood sugar maintained a level or fell slightly but among individuals who had diabetes, definite increases in values for blood sugar accompanied the absorption of the glucose (Table IV).

The metabolic changes in Case 20 graphically represented are shown in Figure 2.

Sucrose administered parenterally to man is not utilized, but it has been shown by Keith Wakefield and Power that 97 per cent to 98 per cent of it is excreted in the urine within 24 hours. If sucrose is instilled into distal segments of the colon its subsequent excretion in the urine will be evidence of its absorption by the colon. The invertase hydrolysis method of determination of su-

observations were not recorded in Tables V or VI

Observations made on an individual who had undergone colostomy at the level of the sigmoid disclosed that 5 grams of sucrose instilled into the distal colonic segment resulted in urinary excretion of sucrose, and that this excretion continued for 48 hours, 382 milligrams were excreted in the first 24 hours, and 273 milligrams in the second 24 hours. This indicates the slowness of absorption of sucrose. The individual mentioned in the foregoing was 1 of 5 who had undergone colostomy at levels ranging from the sigmoid to that of the middle of the transverse colon. Excretion of sucrose in the urine ranged from 2.6 per cent to 12.5 per cent in 24 hours, and from 13.1 per cent to 19.3 per cent in 48 hours; the percentages are based on amounts instilled into the distal segments of colon. It was observed that the higher the colostomy and thus the larger the absorbing surface of colon the smaller was the fraction of the total amount of sucrose instilled which was excreted in the urine. This suggested that much of the sucrose not recovered in the urine might have been hydrolyzed to dextrose and levulose, and absorbed as such since only small

Fig. 3. Metabolic changes in Case 20

fractions, ranging from 0.023 grams to 0.135 grams remained in the colonic segments at the end of the observation (Table V)

Arsenic instilled as neoarsphenamine, in quantities of 0.15 grams, into the distal colonic segments of 7 persons who had undergone colostomy at the level of the sigmoid resulted in the disappearance of 25 per cent to 100 per cent of the instilled arsenic within 4 hours; the arsenic of the residual fraction was determined by the Osterberg modification of the Gutzeit method. Of arsenic instilled into 2 persons who had undergone cecostomy, 69 per cent and 100 per cent respectively, disappeared in 4 hours. Excretion of arsenic in the urine did not occur in these experiments. However when the amount of neoarsphenamine instilled

Fig. Anatomical condition after double barrel or loop colostomy and method of using catheters

the distal colonic segment the same determinations were made at hourly intervals for 3 hours, with an additional determination of blood sugar at the first half hour. Table IV shows that in each case mentioned in the foregoing there was an increase in heat production and in 3 instances there was an increase in respiratory quotient above the basal levels at some point during the disappearance of 9.42 to 48.75 grams of glucose from the distal colonic segments.

Among individuals whose carbohydrate metabolism was not impaired the values for blood sugar maintained a level or fell slightly, but among individuals who had diabetes, definite increases in values for blood sugar accompanied the absorption of the glucose (Table IV).

The metabolic changes in Case 20 graphically represented, are shown in Figure 2.

Sucrose administered parenterally to man is not utilized but it has been shown by Keith, Wakefield and Power that 97 per cent to 98 per cent of it is excreted in the urine within 24 hours. of the colon in the following 5 hours although urinary excretion of the dye occurred at that time.

Glucose intravenously administered in amounts of 25 grams was not excreted by the distal part of the colon.

Sucrose intravenously administered in amounts of 5 grams was not excreted by the colon in the subsequent 18 or 19 hours, although urinary excretion of 87 per cent to 89 per cent of the administered amount occurred during that time.

Results with arsenic are given in Table VIII.

COMMENT

The undoubted functions of the colon consist of storage and propulsion of the stool secretion of mucus to facilitate its passage, and absorption of water (17-24). There is additional experimental evidence to indicate that from cæcum to anus definite amounts of protein carbohydrate, salts, metals, anaesthetics, and drugs may be absorbed (4, 5, 7, 22, 27, 32, 33). Bacteria may be absorbed rapidly from the colon, and experiments on animals indicate that rectally introduced glucose results in a greater deposit of carbohydrate in the liver than occurs after its intravenous administration (8, 24, 28).

Functionally the proximal and distal halves of the colon are regarded as dual organs. The proximal half is regarded as the absorptive portion and the distal half as the organ of

storage and propulsion. This division of function is based on the following observations: (1) The proximal part of the colon is developed from the midgut along with the absorptive small intestine, while the distal part is derived from the hindgut. (2) The proximal part of the colon is of larger caliber, and its walls are thinner than the smaller, thick-walled distal portion. (3) The prevailing types of movement in the proximal part of the colon, particularly at the cæcum, are churning and antiperistalsis, whereas in the distal part the prevailing type of movement is propulsive. (4) The content of the proximal part of the colon

is liquid whereas that of the distal part is solid or semisolid.

Opinion is still divided as to whether material, other than water which disappears from the lumen of the colon, is actually absorbed. It has been pointed out that the major fallacies in the assumption that colonic absorption is the cause of this disappearance, are (1) the probability of antiperistalsis carrying the test substance up into the absorbing ileum (2) the inability completely to cleanse the undivided colon, and the consequent questionably complete removal of the unabsorbed fraction of test substance and (3) the possibility of destruction of the test substance by bacterial action.

In our work these objections were overcome by (1) the operative division of the colon, which precluded the possibility of loss by antiperistalsis (2) the shortness of the colonic segment, from which a test substance could be completely removed immediately after its introduction (3) the possibility of complete

cleansing of the easily accessible colonic segment so that the remaining intestinal content is incapable of fermenting glucose by incubation *in vitro* (4) the use of further criteria of absorption, other than disappearance of the test substance from the colonic lumen.

The further criteria just mentioned require comment. The evidences of absorption of methylene blue, of atropine, and of arsenic, which were employed have been recorded in applicable tables.

Much dissenting opinion exists over the question of colonic absorption of glucose (3, 4, 6, 9, 10, 11, 12, 16, 17, 18, 20, 21, 23, 25, 26, 27, 28, 29, 30, 31). Failure of values for blood sugar in the peripheral blood to increase during the disappearance of glucose from the lumen of the colon has been the basis of some conclusions as to the failure of the colon to absorb glucose. Actually if the factors by means of which sugar is removed from the blood stream are not impaired, the values for peripheral blood sugar would be expected to be unaltered or to be perhaps slightly reduced due to pancreatic stimulation during the colonic absorption of glucose. This is what occurred during our observations of subjects who were free of diabetes. On the other hand in the observations on a diabetic subject, the values for peripheral blood sugar definitely increased during the absorption of glucose from the colonic segment. In addition, increases above the basal level in the respiratory quotient or in heat production in calories per square meter per hour or in both, occurred at some time during the colonic absorption of glucose, in all observations.

If a sugar which is not metabolized in the body is absorbed unchanged by a colonic segment, its subsequent excretion into the urine, and its recovery therefrom is definite proof of absorption. For that purpose sucrose was instilled into distal colonic loops and recovered unchanged, in the urine in significant amounts in all observations. Absorption of this substance was shown to be extremely slow since urinary excretion, although beginning within an hour from the time of introduction of the sucrose into the colonic loop continued for 48 hours, but could be terminated by removing the sucrose from the colon. Only a portion of

the instilled sucrose was absorbed as such by the colonic segment. It is possible that the remainder may have been hydrolyzed to dextrose and levulose and absorbed as such.

Numerous metals and metallic salts have been shown to be excreted in the feces. Our work on excretion was designed to determine whether the same substances shown to be absorbed by the distal part of the colon, were excreted by the same segment when introduced orally or intravenously. The results with methylene blue, glucose, sucrose and arsenic have been presented.

CONCLUSIONS

Distal segments of the generally regarded least absorptive or distal half of the colon of man were shown to absorb methylene blue, which subsequently was excreted in the urine, atropine, which caused pupillary dilatation and decreased salivation, sucrose, which subsequently was excreted in the urine, arsenic as neoarsphenamine, which subsequently was excreted in the urine and in the stools from the proximal part of the intestine, and glucose, which disappeared from the colonic segment, accompanied by an increased respiratory quotient or increased heat production, or both. In the presence of impaired utilization of carbohydrate, increases in values for peripheral blood sugar accompanied this process.

Distal segments of the colon of man did not excrete methylene blue, which had been orally administered in amounts sufficient to appear in the urine, glucose, when 25 grams of it had been intravenously administered, sucrose when 5 grams of it had been intravenously administered. Arsenic, when administered orally as treparsol was excreted by distal colonic segments in amounts which in some instances exceeded the urinary excretion over the same period of time.

SOME PRINCIPLES OF LOCAL ANÆSTHESIA

L. ADÁM, M.D. BUDAPEST HUNGARY
 Professor of Surgery University of Budapest

PAIN is a psychic experience well known to all of us (Foerster). Undoubtedly, pain is often a warning that our body or some organ of it is diseased and needs rest. Pain is, however not always a bene factor, it may also be a useless torturer. As to operative pain and pain of incurable disease, the ancient Hippocratic adage "*divinum est opus sedare dolorem*" has remained valid to this day.

Physical correlative of the psychic experience of pain sensation consists in an excitation process of the afferent nervous system (Foerster).

The nerves supplying the individual organs are for the most part well known, unless they are thoroughly understood good anaesthesia is impossible. No doubt there may be a great difference between the sensitiveness of one individual and another or of one organ and another but if a really good anaesthesia is to be obtained this difference should not be relied upon but each individual and each organ should be considered sensitive not only skin muscle fascia, bone joints pleura peritoneum, but also stomach bowel, bladder, parenchymatous organs vessels and so on. Sensory nerve fibers can be demonstrated in the stomach bowel vessels, lungs and so on—although not in cartilage—but very probably the receptors of the bowel are different from those of the skin. Pressure crushing stinging, burning of the skin are painful whereas the same stimuli cause no pain if applied to the bowel or to the lung. It is likely however that contractions stretching anaemia of the bowel sufficient duration and summation of various stimuli changes in the vicinity are capable of producing pain.

It must be stressed that even the smallest sensitive field during operation should receive due care. Sensitivity of the smallest spot may spoil the entire effect of anaesthesia, for the patient is not conscious of the painless phases of the operation and remembers only the pain conveyed from the sensitive part.

I have been studying the question of local anaesthesia for more than 25 years. At the surgical clinic of Professor Dollinger we performed 6 000 operations under local anaesthesia—95 per cent of all cases—as reported by Professor Dollinger in 1913 at the International Congress of Surgeons in London. This number has not been reached by any other surgeon as yet. Together with my 1 200 cases operated upon at the Zita Hospital 7 200 operations have been performed under procaine anaesthesia, tutocaine has been used in 6,675 cases, nupercaine in 4,940, pantocaine in 4,982, this makes a total of 23 797 major operations and if I add our 8 000 operations performed on out patients I can report 31,797 operations performed under local anaesthesia, without a single fatality during operation. This is such a great number and the result is so excellent that it seems worth while to draw a few useful conclusions. Methods have been amply commented upon in the works of Schleich, Braun, Redus and Pauchet, therefore I only wish to call attention to some practical points.

CHOICE OF ANÆSTHETIC

The first important problem is the choice of a good anaesthetic. Since I had no fatality with procaine, the question may be raised, why I abandoned it and why I later abandoned tutocaine and nupercaine as well. I can easily answer that "better" is the enemy of "good." In any case it seems worth while to examine this problem more closely.

What is required of a good anaesthetic? This question I answered in my lecture at the Congress in Sopron in 1929 as follows:

1. It must be a substance capable of paralyzing the nerve tissue at a low concentration, without being a protoplasm poison to the other tissues.

2. The anaesthetic possesses a specific affinity to the nerve tissue and if it enters the circulation it may seriously intoxicate the central nervous system therefore it must be

retained at the site of injection as long as possible.

3 The change brought about in the sensory nerve by the anæsthetic must cease after a certain time without leaving a trace

4 The anæsthetic must be transformed locally by the tissues in order to be released into the circulation in a detoxified state.

5 From a surgical point of view it is important that it be water soluble, boilable, and not liable to decomposition during sterilization. It must not irritate the tissues or cause pain on injection. It must mix with epinephrin in order to be retained locally.

Even though an anæsthetic fulfills all these requirements we must still take into account the fact that the more efficacious an anæsthetic is, the greater its toxicity. In the living organism, however, toxicity of many compounds becomes modified under the influence of certain factors. It must be specially emphasized that the diffusion speed of an aqueous solution depends on the quality of the dissolved substance on the permeability of the membranes separating the solutions, and on the concentration of the solution.

The main cause of my changing anæsthetics, therefore, was my endeavor to use substances of the lowest possible effective concentration in order to depress the diffusion speed. In a major operation 150 to 180 cubic centimeters of anæsthetic solution is required. If a 1 per cent procaine solution is employed this means not only the introduction of 1.5 to 1.8 grams of foreign substance into the organism but also the use of a 1 per cent solution the absorption of which on account of its relatively high concentration is quicker than that of a 0.25 per cent tuteocaine or a 0.1 per cent pantocaine solution. This will certainly increase the toxicity. That this is true is evidenced by the fact that palpitation, pallor, diffuse sweating, rapid pulse, even nausea and vomiting during or shortly after anæsthesia were almost constant concomitant symptoms of procaine anæsthesia, whereas since I have used the solutions of low concentration the symptoms mentioned have become an extremely rare occurrence.

Second the anatomical site of the operation needs careful consideration. On the head

neck or near the spinal column one cannot, with impunity, use as great quantities of anæsthetic as may be used far from the central nervous system e.g. on the extremities, whence the anæsthetic must pass many more cells before reaching the central nervous system and in this way be more likely to become thoroughly modified or detoxified.

Not only have intoxications ceased to appear in our patients but better anæsthetic effects are obtained even in the hands of the young members of the staff of my clinic. This improvement I am convinced, is due not only to ample opportunity afforded staff members to see and to learn the technique of anæsthesia and the suggestive influence on new patients of those already operated on, but also to the fact that a sufficient quantity of this diluted anæsthetic to anæsthetize any operative field may be safely used. Nevertheless I would warn against injecting too great an amount at once: the dose should remain far below the toxic dose. If the patient should feel pain during operation the few milligrams of anæsthetic which will have been already detoxified allow for the injection of a considerable amount of additional anæsthetic solution. This continuous supplementing dosage according to the needs, makes it possible to complete under local anæsthesia any operation started under local anæsthesia. The fact that in complicated operations of long duration we do not inject large quantities of anæsthetic at once may account for our record of not a single fatality in a vast number of cases.

METHODS

With adoption of certain modifications, I returned to and use extensively the Schleich, Hackenbruch and Oberst methods—the latter of course, without tourniquet—all methods of nerve block anæsthesia—trigeminal, cervical, Kulenkampff plexus, the Keppler-Haertel methods and so on—carried out as well endoneurally as perineurally. In the abdominal cavity I use the Braun anæsthesia of the solar plexus of the hypogastric plexus, also parasceral anæsthesia and infiltration of mesenteric attachments. Paravertebral anæsthesia I now use exclusively in kidney operations.

Complicated methods in general are likely to fail. Their drawback is that in case of failure another method has to be resorted to, and this must be one performable in the operative field. By complicated method I do not mean a block anæsthesia in which the nerves are outside the operative field but may be reached without changing the patient's posture to any great extent. In general, anæsthesia should be brought nearer to the field of operation.

I abandoned not only paravertebral anæsthesia, but also trunk anæsthesia of the major and minor splanchnic nerves (suggested formerly by myself), and the solar plexus anæsthesia of Kappis. I do not employ the high sacral anæsthesia as recommended by Schuster, nor the method of pouring anæsthetic solution into the abdominal cavity as suggested by Seidel. I shall not return to spinal anæsthesia and I am not inclined to use even the controllable form as described by Kirschner (control by air sufflation) as long as I hear that there is one fatality in each 300 to 500 cases and that excruciating headaches lasting for days and bladder paralyses are often observed.

OBJECTIONS AND CONTRA INDICATIONS TO LOCAL ANÆSTHESIA

What are the drawbacks of local anæsthesia?

It is said that it requires a special training. This is true, but it is not a disadvantage. Moreover in most operations the methods have been so greatly simplified that they may be easily learned.

Occasionally fall of blood pressure or certain toxic symptoms will occur. These however, become progressively more uncommon, moreover, they cannot be compared with troubles observed in general anæsthesia.

It has been asserted too that some greater vessel may be injured. With some care this can easily be avoided and even if an injury occurs it will cause no serious trouble, provided the injury is perceived and no anæsthetic is injected into the vessel. In infiltrating the deep layers I never use too sharp needles and in this way the orientation as to the layers is made easier. Tissue necrosis

caused by anæsthetics has also been described, I myself never saw a single case of this and I believe that those who have observed it must have infiltrated tense tissues or used great amounts of some highly concentrated fluid.

Suppuration cannot be placed to the account of local anæsthesia, for both syringe and solution may and should be adequately sterilized.

What are contra indications for infiltration anæsthesia?

Most treatises on this topic mention malignant tumors, sepsis, inflammatory diseases, youth, and obesity or hysteria in women. In our day a malignant tumor is not considered a contra indication by the majority of surgeons for, if performed far enough from the neoplasm, inoculation need not be feared. Moreover operations for cancer of the tongue, cheeks, tonsils and throat have lost their bad reputation since the introduction of local anæsthesia.

In my opinion general anæsthesia is contra indicated in septic patients, as for the rest, I never saw suppuration at the site of the injection.

No doubt active hyperæmia increases excitability of sensory nerves whereas passive hyperæmia depresses the same. Nevertheless, I do not recommend the classic Oberst anæsthesia, and even less do I recommend applying the constricting bandage to an anæsthetic field since constriction itself is painful. Many surgeons are disinclined to employ local anæsthesia in inflammatory conditions because they fear that forcing the solution into the tense tissue may cause pain, they are afraid also that infective matter may be conveyed into healthy tissues, and give rise to a spreading infection. I never have been restrained by inflamed tissues from operating under local anæsthesia and I never saw any unfortunate consequence. Of course if the field is of small size, I prefer circular infiltration in the healthy tissues or I perform block anæsthesia if feasible, but if it seems necessary I do not refrain from infiltrating the inflamed tissue. In such cases I use a very fine needle and I inject the solution at a slow rate. I do not enter healthy regions from inflamed ones. In my experience infiltration of inflamed tissues never caused spreading of the infection, it has rather tended

toward quicker amelioration or even subsidence of the inflammation, possibly by abolishing pain. Of course I readily admit that there are cases in which a superficial ethyl chloride inhalation is to be preferred to a more complicated local anaesthesia (e.g. mastitis and so on)

Hohmeier and a few other surgeons describe a method of infiltration which consists in pushing the needle forward until bone contact is felt and infiltrating the layers while pulling back the needle. This method is not too gentle. The solution should always precede the needle, because in this way infiltration is entirely painless and injury to vessels is not likely to occur.

Anaesthesia must be induced without causing pain. Methods using intravenous or other kinds of narcosis for performing local anaesthesia are needless. Local anaesthesia needs gentleness, patience, and anatomical knowledge. If it fails the patient should be given ethyl chloride or ether but he must not be allowed to suffer. I have simplified the technique of inducing anaesthesia to such an extent that the patient feels only one or at most two superficial needle pricks. In this manner I am able to operate on a steadily increasing number of children under local anaesthesia.

I often read that fat or hysterical women are not suited for local anaesthesia. I cannot agree with this. In fat women I consider narcosis contra-indicated whereas the majority of hysterical women are very well suited for local anaesthesia, especially if they are kept in the hospital for a few days before being operated upon.

I have not observed any untoward effect from block anaesthesia either in diabetic or in arteriosclerotic patients. Epinephrin however injected near to necrotic tissues, may cause spread of necrosis.

ADVANTAGES AND ABSOLUTE INDICATIONS

And now what are the advantages of local anaesthesia? A point of economy is that no medical assistant is needed during operation or until the awakening of the patient. The operation is not complicated by a simultaneous procedure the narcosis, which is fraught with a graver danger than the operation itself

since although it is almost out of the control of the operating surgeon he is nevertheless responsible for its risks.

Local anaesthesia can be employed in all cases in which general anaesthesia would be dangerous. It has a great importance in bone fractures. If 20 cubic centimeters of a 0.1 per cent pantocaine solution is injected between the bone ends, pain and muscular contraction promptly cease and the fracture may be easily and painlessly reduced. No block or circular infiltration anaesthesia is needed. In general medical practice it saves a great deal of suffering. The general practitioner cannot be required to perform under narcosis lumbar or cisternal puncture or puncture of the pleural or peritoneal cavity of joints of a paranephritic abscess (nor is the practice indicated) but he should be required to anaesthetize the skin at the puncture site and the entire way of the needle. In this way breakage of needles will be avoided and the patient will not be in fear of a future repetition of the procedure. The argument that the patient has to suffer a prick even if anaesthetized and that a puncture is performed so quickly as to make anaesthesia superfluous does not hold. The single layers, especially the pleura and the peritoneum are very sensitive, and even after the needle has been introduced, the slightest movement of the needle during tapping may cause considerable pain.

Local anaesthesia is indicated in all operations if there is no particular contra-indication—psychic causes, greater simplicity of general anaesthesia—because it is simpler and safer.

There are certain operations which I never perform under general anaesthesia. In heart disease, emphysema, bronchitis, arteriosclerosis, kidney disease, in impaired liver function or in bad operative risks narcosis is contra-indicated. Cosmetic operations, and interventions that are not absolutely necessary (removal of scars, benign tumors) certain plastic operations, herniorrhaphies—especially umbilical hernias of fat women—I perform exclusively under local anaesthesia, because I consider it inexcusable to expose the patient to the danger of narcosis if the same operation can be performed safely under local anaesthesia. The same applies to trepanation,

OUR CASES SINCE 1926

Total Linear infiltration		11,036 1,778	490 (3.5 per cent)
Total Narcosis		(80.9 per cent) 14,320 (16.6 per cent) 3,023	

Total number of operations 8,233

operations on the face, mouth neck, thorax and the genito-urinary apparatus, which operations I perform almost exclusively under local anaesthesia. I employ narcosis only in certain abdominal operations and in operations on the extremities if local anaesthesia has proved unsatisfactory or if narcosis is simpler and not contra indicated in long standing jaundice, however, narcosis may be followed by serious injury to the liver

I readily admit that postoperative pneumonia is observed also in patients operated upon under local anaesthesia, it shows, however, a more favorable course and is more easily treated. There is no doubt that local anaesthesia is less likely to be followed by postoperative heart, liver, and kidney damage.

It is not fair to compare mortality of operations performed under general and local anaesthesia, respectively, because many poor risks are operated upon under local anaesthesia who were refused operation, or they were operated upon under narcosis and died. In seriously impaired liver function the results of local anaesthesia are conspicuously better than those of general anaesthesia.

What is still to be required of an ideal anaesthetic?

In my opinion it would be of great benefit if the anaesthetic or at least the hypaesthetic effect could be prolonged. The effect is sufficient for the performance of the most extensive operations, it would be desirable, however, if the operative field could be made painless for at least 24 hours.

After narcosis, the patient, being still under the narcotic effect, does not cough, whereas in local anaesthesia, after pain sensation of the wound has returned, the patient does not breathe deeply and does not ventilate his lungs. If, however, the pain could be abolished for 6 to 18 hours, the patient would dare to move to breathe deeply. In this way many bed sores, many cases of pneumonia could be prevented and the patient could be spared much pain, for pain decreases with each additional hour elapsing after operation. After 24 hours the wound does not ache at all. In my opinion therefore, after anaesthesia, a painless period lasting 24 hours should be aimed at. In this respect nupercaine opened a new perspective and if we succeed in securing a 24 hour painlessness the ideal goal of entirely painless operative healing will be reached.

toward quicker amelioration or even subsidence of the inflammation, possibly by abolishing pain. Of course I readily admit that there are cases in which a superficial ethyl chloride inhalation is to be preferred to a more complicated local anesthesia (e.g. mastitis and so on).

Hohmeier and a few other surgeons describe a method of infiltration which consists in pushing the needle forward until bone contact is felt and infiltrating the layers while pulling back the needle. This method is not too gentle. The solution should always precede the needle, because in this way infiltration is entirely painless and injury to vessels is not likely to occur.

Anesthesia must be induced without causing pain. Methods using intravenous or other kinds of narcosis for performing local anesthesia are needless. Local anesthesia needs gentleness, patience and anatomical knowledge. If it fails the patient should be given ethyl chloride or ether, but he must not be allowed to suffer. I have simplified the technique of inducing anesthesia to such an extent that the patient feels only one or at most two superficial needle pricks. In this manner I am able to operate on a steadily increasing number of children under local anesthesia.

I often read that fat or hysterical women are not suited for local anesthesia. I cannot agree with this. In fat women I consider narcosis contra-indicated, whereas the majority of hysterical women are very well suited for local anesthesia, especially if they are kept in the hospital for a few days before being operated upon.

I have not observed any untoward effect from block anesthesia either in diabetic or in arteriosclerotic patients. Epinephrin, however injected near to necrotic tissues, may cause spread of necrosis.

ADVANTAGES AND ABSOLUTE INDICATIONS

And now what are the advantages of local anesthesia? A point of economy is that no medical assistant is needed during operation or until the awakening of the patient. The operation is not complicated by a simultaneous procedure, the narcosis, which is fraught with a graver danger than the operation itself

since, although it is almost out of the control of the operating surgeon, he is nevertheless responsible for its risks.

Local anesthesia can be employed in all cases in which general anesthesia would be dangerous. It has a great importance in bone fractures. If 20 cubic centimeters of a 0.1 per cent. pantocaine solution is injected between the bone ends, pain and muscular contraction promptly cease and the fracture may be easily and painlessly reduced. No block or circular infiltration anesthesia is needed. In general medical practice it saves a great deal of suffering. The general practitioner cannot be required to perform under narcosis lumbar or costal puncture or puncture of the pleural or peritoneal cavity of joints of a paraneuritic abscess (nor is the practice indicated), but he should be required to anesthetize the skin at the puncture site and the entire way of the needle. In this way breakage of needles will be avoided and the patient will not be in fear of a future repetition of the procedure. The argument that the patient has to suffer a prick even if anesthetized and that a puncture is performed so quickly as to make anesthesia superfluous does not hold. The single layers, especially the pleura and the peritoneum, are very sensitive and even after the needle has been introduced the slightest movement of the needle during tapping may cause considerable pain.

Local anesthesia is indicated in all operations if there is no particular contra-indication—psychic causes, greater simplicity of general anesthesia—because it is simpler and safer.

There are certain operations which I never perform under general anesthesia. In heart disease, emphysema, bronchitis, arteriosclerosis, kidney disease, in impaired liver function or in bad operative risks, narcosis is contra-indicated. Cosmetic operations, and interventions that are not absolutely necessary (removal of scars, benign tumors), certain plastic operations, herniorrhaphies—especially umbilical hernias of fat women—I perform exclusively under local anesthesia, because I consider it inexcusable to expose the patient to the danger of narcosis if the same operation can be performed safely under local anesthesia. The same applies to trepanation.

OUR CASES SINCE 1926

Type of anæsthesia	Site of operation	Number of cases	
		Local anæsthesia	Local anæsthesia + narcotics
Block anæsthesia	Head	387	13
	Neck	509	none
	Thorax	804	8
	Abdomen	190	8
	Upper extremity	181	4
	Lower extremity	337	3
	Hernia	3,660	6
	Rectum	818	none
Brown scolar plasma	Stomach	860	20
	Bile passages	1,053	91
	Spleen	4	none
Mesenteral	Small intestine	91	10
	Colon	11	none
	Appendix	4,018	248
	Female genitalia	20	7
Paravertebral (Rikner-Noskov type) (Fragrant type)	Ribs (thoracoplasty)	8	1
	Kidney	8	2
	Female genitalia	9	1
	Vagina	17	none
Parasacral	Rectum	46	1
	Bladder	23	6
	Prostate	27	5
Total Local infiltration		11,056 1,773	439 (2.5 per cent)
Total Narcosis		(80.9 per cent) 14,730 (18.6 per cent) 3,025	

Total number of operations 8,231

operations on the face, mouth, neck, thorax and the genito-urinary apparatus which operations I perform almost exclusively under local anæsthesia. I employ narcosis only in certain abdominal operations and in operations on the extremities if local anæsthesia has proved unsatisfactory or if narcosis is simpler and not contra-indicated, in long standing jaundice however, narcosis may be followed by serious injury to the liver

I readily admit that postoperative pneumonia is observed also in patients operated upon under local anæsthesia, it shows, however a more favorable course and is more easily treated. There is no doubt that local anæsthesia is less likely to be followed by postoperative heart, liver, and kidney damage.

It is not fair to compare mortality of operations performed under general and local anæsthesia respectively, because many poor risks are operated upon under local anæsthesia who were refused operation, or they were operated upon under narcosis and died. In seriously impaired liver function the results of local anæsthesia are conspicuously better than those of general anæsthesia.

What is still to be required of an ideal anæsthetic?

In my opinion it would be of great benefit if the anæsthetic or at least the hypæsthetic effect could be prolonged. The effect is sufficient for the performance of the most extensive operations, it would be desirable, however, if the operative field could be made painless for at least 24 hours.

After narcosis, the patient being still under the narcotic effect, does not cough, whereas in local anæsthesia, after pain sensation of the wound has returned, the patient does not breathe deeply and does not ventilate his lungs. If, however, the pain could be abolished for 6 to 18 hours, the patient would dare to move, to breathe deeply. In this way many bed sores, many cases of pneumonia could be prevented and the patient could be spared much pain, for pain decreases with each additional hour elapsing after operation. After 24 hours the wound does not ache at all. In my opinion therefore after anæsthesia, a painless period lasting 24 hours should be aimed at. In this respect nupercaine opened a new perspective and if we succeed in securing a 24 hour painlessness the ideal goal of entirely painless operative healing will be reached.

VARIATIONS OF THE FEMALE PELVIS IN RELATION TO LABOR

HERBERT THOMAS, M.D., NEW HAVEN, CONNECTICUT

From the Department of Obstetrics and Gynecology, Yale University School of Medicine

VARIATIONS of the female pelvis which are not abnormalities in the usual sense occur with relative frequency a fact to which I called attention in 1932 (4). A common variation which we have studied is characterized by a shortening of the transverse diameter of the superior strait often associated with an increased anteroposterior diameter. In such pelvis this plane appears essentially round while in some, the anteroposterior diameter is actually increased over that of the transverse making the pelvis of the true dolichopelvic type described in 1886 by Turner.

In 1933 Caldwell and Moloy reported on the anatomical variations of female pelvis and classified them into 4 general groups—the gynecoid, android, anthropoid and platypelloid types. These authors further subdivided their classification to include pelvis which may be admixtures of the types noted and employed such terms as android anthropoid, android-gynecoid, android flat anthropoid-gynecoid, gynecoid flat etc. While these designations are interesting and descriptive it is obvious that for general clinical purposes a more simple classification is essential. I have recently suggested that such a classification can be based chiefly upon the general conformation of the superior strait as is shown in the following grouping:

1 *The female type* The normal female pelvis of other classifications. The superior strait is ovoid in shape, the transverse diameter being more than 1 centimeter longer than the anteroposterior diameter. The pelvis may be classified as large, average or small dependent upon the length of the anteroposterior diameter. If this diameter is 12 centimeters or over the pelvis is designated as large female type. If the diameter is under 10.5 centimeters it is designated as small female type. In rare instances the length of the transverse diameter may be so increased over that of the anteroposterior

diameter as to render a distinctly flattened appearance to the superior strait. In any instance therefore where the transverse diameter is longer than the anteroposterior by 3 centimeters or more such a pelvis is spoken of as flat female type. For example, the anteroposterior diameter being 9.5 centimeters with the transverse diameter 12.5 centimeters the pelvis would be designated small flat female type.

2 *The round type* The superior strait in this type has a distinctly round appearance the transverse diameter predominating in length over the anteroposterior by 1 centimeter or less. The pelvis may be classified as large, average or small, dependent upon the length of the anteroposterior diameter. If this diameter is 13 centimeters or over the pelvis is designated as large round type. If this diameter is less than 11 centimeters it is designated as small round type.

3 *The anthropoid type* The superior strait appears elongated anteroposteriorly. The anteroposterior diameter is longer than the transverse. The pelvis may be classified as large, average or small dependent upon the length of the anteroposterior diameter. If this diameter is 14 centimeters or over the pelvis is designated as large anthropoid type. If this diameter is less than 11.5 centimeters it is designated as small anthropoid type.

To differentiate readily large and small pelvis in these types we may summarize as follows:

Large pelvis

Female Type—Anteroposterior diameter of 12 centimeters or over

Round Type—Anteroposterior diameter of 13 centimeters or over

Anthropoid Type—Anteroposterior diameter of 14 centimeters or over

Small pelvis

Female Type—Anteroposterior diameter less than 10.5 centimeters

Round Type—Anteroposterior diameter less than 11.0 centimeters

Anthropoid Type—Anteroposterior diameter less than 11.5 centimeters

the external conjugate measured 17.5 centimeters with true anteroposterior diameters of 11.0 11.0 12.5 11.5 11.0 10.5 9.5 9.5. In 5 instances the external conjugate measured 17.0 centimeters with a true anteroposterior diameter of 11.0 11.0 12.0 12.5 11.5. These figures show the impossibility of establishing any true relationship between the length of the external conjugate diameter and the true anteroposterior diameter of the superior strait.

With regard to external pelvimetry of the pelvic outlet the situation is different. Here the bony points to be measured are easily palpable externally and our mensuration of the diameters of the outlet should be reasonably accurate. I believe therefore that the most practical methods of determining the dimensions of the female pelvis in the living are those of roentgen pelvimetry of the superior strait and external pelvimetry of the pelvic outlet.

Perhaps at this point a word should be said with regard to the determination of the diagonal conjugate diameter by means of vaginal touch. We have found that in primiparous patients this is usually an unsatisfactory procedure due to the rigidity of the soft parts and to the discomfort experienced by the patient. Furthermore it is obvious that in most of the round type and anthropoid type pelvis, the procedure is of little use as the fingers of the examiner are not, as a rule sufficiently long to reach the sacral promontory.

In studying the character of the labor in 100 primiparous women whose pelvis come under the classification just noted the following facts were observed:

PELVES OF THE FEMALE TYPE

Of the 49 cases presenting pelvis classified as female type (43 white, 7 colored) 39 were delivered spontaneously and 10 by operative procedures. In 7 instances the occiput entered the posterior half of the pelvis (15 per cent of vertex presentations). This occurred 3 times in the average female type, 3 times in the small flat female type and once in the small female type.

PELVES OF THE ROUND TYPE

Of the 37 cases presenting pelvis classified as round type (32 white, 5 colored) 26 were

delivered spontaneously and 11 by operative procedures. In 7 of this group (7 of 34 vertex presentations or 20 per cent) the occiput entered the posterior half of the pelvis.

PELVES OF THE ANTHROPOID TYPE

Of the 15 cases presenting pelvis classified as anthropoid type (12 white, 3 colored) 12 were delivered spontaneously and 3 by operative procedures. In 8 cases (8 of 14 vertex presentations, or 57 per cent) the occiput entered the posterior half of the pelvis.

DURATION OF LABOR

Many factors influence the duration of labor in primiparous patients, such as the strength and frequency of the uterine contractions, the size of the fetus, the malleability of the fetal head etc. However the size and shape of the pelvis is one of the important factors. While no definite conclusions can be drawn from the following data concerning the length of labor in the series in question the figures as given may be of interest:

<i>Female type series</i>	hours
Average duration of labor for the series	16½
Average duration of labor in large type	18½
Average duration of labor in small type	20½
<i>Round type series</i>	
Average duration of labor for the series	17½
Average duration of labor in large type	19½
Average duration of labor in small type	21½
<i>Anthropoid type series</i>	
Average duration of labor for the series	13½
Average duration of labor in large type	14½
Average duration of labor in small type	12½

OCCIPITOPOSTERIOR POSITIONS

In 1932 I called attention to the intimate association between occipitoposterior varieties and the transversely contracted (round and anthropoid type) pelvis, and reviewed 16 consecutive cases in which occipitoposterior positions had occurred consecutively. An analysis of these cases according to the classification given shows the types of pelvis presented:

Average anthropoid type	4
Large anthropoid type	1
Average round type	8
Small round type	2
Small female type with slight asymmetry	1

In the paper noted above the statement was made that 'transverse contractions of the

pelvic inlet, either real or relative are far more frequent than hitherto supposed and have a most important place in occipitoposterior positions." In the following year I pointed out that actual or relative shortening of the transverse diameter of the superior strait results in a limitation of space that is relatively greater in the anterior than in the posterior half of this plane and that under these circumstances it seems obvious that the occiput in its descent will enter the pelvis in its posterior half. This viewpoint was substantiated by the opinion of Caldwell and Moloy who state that "in the anthropoid type of pelvis engagement is possible only in the anteroposterior diameter as compensation exists in the posterior pelvis the anterior part of the inlet being narrow."

Several observers have pointed out that early in labor an occipitoposterior position is more common than is generally recognized. Thus Potter (3) who because of his unusual technique of delivery by version and extraction makes vaginal examinations early in labor, reports in a series of 515 cases an occipitoposterior position in 166 or 32 per cent. Danforth (2) in a recent review of 1,565 cases noted this position in 443 or 27.1 per cent. My own opinion is that in certain varieties of pelvis such as the anthropoid round, small female and flat female types the incidence of this position is very high and that the general incidence early in labor is somewhere between 35 and 50 per cent.

The incidence of occipitoposterior position in pelves of the small female type and the flat female type as noted in 4 cases of the present series deserves comment. In the former the shape of the superior strait usually approximates that seen in the small round pelvis which, I am convinced, favors occipitoposterior position while in the flat female type the abnormal projection forward of the sacral promontory which characterizes this variety unquestionably forces the occiput to occupy the posterior half of the pelvis.

The query may well be made as to why in the present series occipitoposterior position early in labor does not show greater incidence. A number of factors may explain this. In the first place these patients were delivered by the house staff whose examinations from be-

low are usually limited to rectal touch. It is obvious that many occipitoposterior positions may be thus overlooked, particularly early in labor when the cervix is but partially dilated. Secondly many patients do not enter the hospital until well advanced in labor and when seen by the examiner spontaneous internal rotation will have already taken place.

CONCLUSIONS

The present study of the pelvis in 135 primiparous women, 100 of whom have been delivered emphasizes the following

- 1 The incidence of anatomical variations of the pelvis is of frequent and significant occurrence. In this group the so called "normal" female pelvis of other classifications occurred in but 52 per cent of cases.

- 2 Because of the frequency of the incidence of anatomical variations, a simple, working classification is necessary and the one presented here is both simple and descriptive in its nomenclature.

- 3 An accurate and practical survey of the female bony pelvis should include roentgen pelvimetry of the pelvic inlet and external pelvimetry of the pelvic outlet.

- 4 The incidence of occipitoposterior position early in labor is undoubtedly greater than is generally believed. In certain of the pelvic variations such as the anthropoid type it is unusually high.

- 5 The important rôle played by the shape of the superior strait in the production of occipitoposterior position is again emphasized.

- 6 The importance of accurate pelvimetry in every primiparous woman is again demonstrated. The practice of scientific obstetrics presumes a knowledge of all the facts that are essential for the successful outcome of labor and the important part played by the size and shape of the bony pelvis needs no emphasis.

Fig. 2. Drawing to illustrate the exposure by blunt dissection of the prevesical space, anterior surface of the prostate and membranous portion of the urethra. Distention of the bladder by the balloon and splinting of the urethra by the catheter help very much in this dissection. a, Shows the general anatomical relationships with the bladder distended and the catheter in place. b, Illustrates how the membranous urethra is opened after it has been isolated and the contained catheter is clamped and divided.

Cystectomy a Method of Retroprostatoseminal Vesicuocystectomy—FRANK HINMAN

CLINICAL SURGERY

FROM THE UNIVERSITY OF CALIFORNIA HOSPITAL

CYSTECTOMY, A METHOD OF RETROPROSTATOSEMINAL VESICULOCYSTECTOMY

FRANK HINDMAN M.D. F.A.C.S. SAN FRANCISCO CALIFORNIA

I CAN find very few descriptions of the operation of cystectomy. The removal of an exstrophic bladder requires no particular technique. The removal of a malignant bladder however is a different matter. The malignant bladder should be removed intact unopened and with the least possible manipulation. Drainage of the pelvic space afterward is equally important as pointed out by the late R. C. Coffey.

There are two routes by which the bladder can be removed—the perineal and the suprapubic. The perineal route is indicated in men with carcinoma of the trigone or neck of the bladder associated with involvement of the prostate, either of which may have been primary. (The vaginal route is indicated in women with cancer of the urethra and vagina.) When this involvement is extensive and the man's pelvis is frozen with cancer the condition probably is inoperable. Such cancers can be removed completely neither suprapubically nor perineally and radical surgery should not be attempted. In less advanced conditions radical removal is possible. When involved the prostate and vesicles can be freed from the rectum more easily through the perineum than suprapubically. When the prostate and vesicles are uninvolved or only slightly so their removal with the bladder by the method to be described is much easier through the abdomen than through the perineum. Some patients with associated vesical and prostatic involvement can be operated on to advantage by a combination of the two routes freeing of the prostate and vesicles perineally and then enucleation of the bladder prostate, and vesicles as one mass suprapubically. The suprapubic route is commonly employed for cystectomy in cancer of the bladder the usual procedure being to free the fundus of peritoneum isolate the vesical arteries and ligate them and then peel the bladder from the vesicles and prostate.

The following method is indicated for those cases of primary cancer of the bladder which require total cystectomy and in which the urine has been diverted (uretero-intestinal implantation) in order that this might be done. In all cases of this type even though the neck of the bladder and the prostate are not invaded apparently the radical removal of the bladder prostate and vesicles intact will insure more completely the removal of all the cancer. The method is retrograde as compared to the suprapubic procedure in common use and aside from certain advantages of technique, has the additional advantage of the least possible manipulation of the bladder.

Description of the method of retrocystectomy. The bladder is washed out and left empty. A special balloon catheter (Fig. 1) is passed well up into the bladder 200 cubic centimeters of mercurousal (or air if preferred) is injected into the balloon and the catheter is connected with tubing which is clamped off in a basin alongside the table so

Fig. 1. Drawing of a home-made catheter-balloon. A finger cot or the finger of a surgeon's glove is tied over the end of a No. 22 or 24 soft rubber urethral catheter.

Fig. 3. Illustrates how the balloon and catheter are used for traction. a, Urethral and prostatic tissues tied to catheter by circular ligature of heavy silk. b, Shows how traction on clamp and ligature lifts the balloon and neck of the bladder. c, Shows how the prostate and vesicles can be peeled back by blunt dissection when traction is made on the catheter and balloon.

Fig. 4. Drawing which illustrates the complete freeing of the prostate and vesicles. a, View from the side. The vas and vessels on the left side have been clamped and divided. b, View from above. The clamps (No. 1) have been placed on the vesical vessels of the right side. Clamp No. 2 is on the vas.

Fig 5 Drawing which illustrates the bladder completely isolated except for peritoneal and urachal attachments a, View from above showing the four clamps in place on the specimen and the corresponding partner removed after the vasa and vessels had been ligated *en masse* as shown in the depths of the field b Side view showing the only remaining attachment of the bladder to the urachus and neighboring peritoneum.

that a nurse can empty or fill the balloon (when the surgeon desires) and thus collapse or distend the bladder

The suprapubic incision need not be long (4 inches) The long scar of the previous operation (ureteral implantation) is excised for about half its length. The fascia and muscles are divided in the area of the scar down to the prevesical fat. (Care is taken not to open into the peritoneal cavity)

The space of Retzius is opened by blunt dissection with the finger, exposing the anterior surface of the prostate and bladder The lower anterolateral wall of the bladder is freed similarly By dissecting under the pubic arch, the apex of the prostate is localized (There should be no bleeding) Following the capsular surface of the prostate at the apex around each side enables one to free completely and encircle with the finger the membranous portion of the urethra. This must be done carefully, well up under the symphysis and at the apex of the prostate because the rectum may be perforated easily by the tip of a finger forced behind the prostate in the wrong line of cleavage The catheter outlines the urethra and aids in making this dissection When the apex of the prostate and the adjacent portion of

the membranous urethra are free so that they can be encircled with the finger the urethra (with the catheter in it) is doubly clamped and then divided (as is the catheter) between the clamps (Fig 2)

The clamp on the distal end is replaced by a braided silk suture by which this cut end of the catheter can be pulled well into the pelvis to serve after being perforated in a few places as a drainage tube after the bladder has been removed (Note discussion of this point under drainage.)

The clamp on the proximal end attached to the balloon is used for traction and in order that this purpose be fully accomplished, the urethral tissues and apex of the prostate are pulled up on the catheter by clamps on each side and anchored to the catheter by a circular ligature of heavy silk (Fig 3 a), the ends of which are tied to the clamp on the catheter so that the two together give good traction (Fig 3 b and c)

In the plane of separation of the fascia of Denonviller, just as in perineal prostatectomy, the prostate can be peeled from the rectum to the area of attachment of the seminal vesicle and vas on each side. The fascial layer covering the right vesicle is incised and this vesicle is freed and delivered The right vas and its vessels are isolated

Fig. 6. Photograph of prostate, vesicles and bladder with balloon catheter in place just as they were removed at operation intact and unopened.

doubly clamped and divided between the clamps (Fig. 4).

The right vascular pedicle of the bladder with the ureter now is isolated by blunt finger dissection and is divided *en masse* between the clamps. The left vas and vesicle and the left vascular pedicle and ureter are clamped and divided similarly. This leaves all the blood vessels which supplied the bladder in the four clamps. The pedicle in the distal one of each pair of clamps is

ligated and the clamp is removed. The proximal clamps are left on (Fig. 5).

The bladder now is attached only to the peritoneum and urachus. The former can be stripped off from below upward with moist gauze, to the point of the attachment of the urachus which is clamped and divided (Fig. 5) completely freeing the unopened bladder. In case the peritoneum is adherent to the bladder because of cancer or inflammation an elliptical area of peritoneum around the site of adhesions can be removed with the bladder and this opening into the peritoneal cavity can be closed without risk of contamination since the bladder has been left intact and unopened.

Drainage of the pelvic cavity left by the removal of the prostate vesicles and bladder should be thorough. Otherwise an abscess may develop in a blind pocket somewhere and lead to septicæmia, as happened in one of my patients. Once the urethral catheter which has been left for drainage (Fig. 5) has been removed, it should not be reinserted. I am not sure that leaving this catheter in originally is not a mistake. It might be preferable to close tightly by suture the open end of the urethra and rely altogether upon supra pubic drains. A perineal drain can be placed easily and gives the advantage of dependent as well as through and through drainage. Subsequent contamination of the pelvic dead space from the urethra or by way of it is likely after the catheter has been removed. This seems to be what happened in the patient just mentioned who developed septicæmia. This man of 72 was in excellent condition for 2 weeks after cystectomy and was up and about after the eighth day. An abscess formed in the pelvis extraperitoneally about this time and he died of septicæmia 3 weeks after operation. Autopsy showed that the cancer had been radically removed. The specimen is shown in Figure 6.

TRANSPERITONEAL NEPHRECTOMY FOR MALIGNANT TUMORS OF THE KIDNEY

LAWRENCE R. WHARTON, M.D., BALTIMORE, MARYLAND
From the Department of Gynecology of the Johns Hopkins University and Hospital

WITHIN the past year or two our attitude toward malignant renal neoplasms has changed. A new suggestion of hopefulness has been introduced. This is because we have learned that massive renal tumors can be made operable by deep roentgen ray therapy. In our experience this applies generally both to Grawitz hypernephromata and Wilms embryomata, and these constitute the majority of renal neoplasms. We have discovered also that other tumors of unusual and bizarre morphology such as cystic carcinoma may respond in a manner which makes their pre-operative irradiation worth while.

The effects of irradiation on the gross and histological characteristics of these tumors and the concomitant physical benefit to the patient have been reported by us elsewhere. Waters, Lewis and Frountz likewise have presented their experience and our clinical conclusions and recommendations coincide.

The salient point of these studies is that the operability of massive renal neoplasms has been vastly increased and the operative mortality reduced. Thus by pre-operative irradiation a ray sensitive tumor which fills three-fourths of the abdomen may be so reduced that it is hardly palpable. In many instances with the shrinking of the tumor the hæmaturia ceases or becomes negligible. During the 3 or 4 weeks required for the course of pre-operative irradiation more over we have an excellent opportunity actually to accomplish something in building up the physical condition and increasing the resistance of these patients. The disappearance of the abdominal mass and the cessation of hæmaturia makes this possible. Consequently in many cases by the time the course of irradiation is completed it is found that the patient may be in fairly good physical condition and the tumor may be safely operable.

It is thus evident that we have entirely revised our pre-operative regimen since we have discovered the value of pre-operative irradiation. Now we have certain definite objects in view and in the majority of instances have some hope of attaining them. Whenever we are successful a great deal of the dread and frightfulness that formerly attended the removal of big malignant renal tumors disappears. In these cases we approach

the operation with a feeling of hopefulness which was unknown two years ago.

THE OPERATION

The final result depends upon one thing—the successful removal of the tumor for we have seen no instance in which radium or the roentgen ray has entirely eliminated a large mass. Now that we have found a means of increasing the operability of these tumors the opportunity and responsibility of the surgeon have become even more significant. For this reason it is imperative that we should review the operative technique of nephrectomy to see whether it fulfills the demands of our new opportunity.

The surgical principle of the operation. In operating upon a renal tumor we have certain very definite objectives. Perhaps we may more clearly realize their importance if we consider for a moment the general pathological characteristics of these tumors.

In the first place they are made up of a mass of friable malignant tissue which is in intimate contact with vascular spaces. At times parts of the tumor actually protrude into the blood stream within a capillary or a large venous trunk. In many types, moreover this tissue is characteristically transplantable and if bits of it are spilled in the operative wound, they grow like weeds. These tumors are also highly vascular and often have abnormally placed blood vessels. They are frequently adherent, grow very large and have thin delicate capsules. These are some of the factors that in the past have made the surgery of renal tumors almost a hopeless proposition. It is for these reasons that nephrectomy has so frequently been followed by a local recurrence and a shower of metastases.

On the contrary, however, these tumors have certain characteristics that make them amenable to treatment. In the first place they seem to metastasize late for the majority of cases show no secondary growths when they reach the surgeon. Then again local invasion is rather uncommon, for the tumor usually remains within its capsule even though it may fill the whole flank. Also most of these tumors are highly sensitive to the roentgen ray and will shrink like magic if they are treated intensively. They can moreover be

Fig. 1 The landmarks and exposure in transperitoneal nephrectomy. The illustration shows the right side, which is more complicated than the left. The abdominal incision must be large and the patient completely relaxed. The posterior peritoneum is incised at some distance from the kidney and the colon is an avascular spot. The mobilization of the peritoneum is continued carefully until one gets an exposure like that shown in Figure 2.

recognized with accuracy by cystoscopic and urographic study. These factors are distinctly favorable and it is only by taking full advantage of them that we have any chance whatever of removing these tumors successfully.

With this picture in mind, it is not hard to formulate an ideal nephrectomy. Such a procedure would allow us to isolate the tumor from its vascular connections before handling the friable mass. By so doing one would avoid massaging particles of the tumor into the blood stream. This would minimize the chance of metastasis. The ideal approach would also give us such wide exposure that we could see the entire blood supply including aberrant vessels, thus lessening the risk of hemorrhage. Also it would furnish enough room to permit the removal of the entire mass intact without rupturing its capsule. This would tend to prevent local recurrence. How do our present methods of performing nephrectomy meet these demands?

There are two available types of operation: the lumbar or extraperitoneal, and the abdominal or

transperitoneal. Of these, the lumbar is by far the most generally used, not only for renal tumors but for all operations on the kidney. Undoubtedly, we all agree that it is the rational method of attacking almost all surgical problems of the kidney because it is extraperitoneal, avoids unnecessary shock and minimizes the chance of peritonitis. But is it the method of choice in operating upon renal tumors? Does it meet the requirements which we must fulfill if we would remove these neoplasms successfully?

Clinical experience and anatomical studies indicate that lumbar nephrectomy violates every one of these principles. Lumbar nephrectomy compels one to attack the tumor before he controls its blood supply. By this approach, the mass must be widely mobilized and manipulated before the renal pedicle can be seen or ligated. Aberrant vessels are often not recognized until they bleed because they lie on the median side of the mass. The last structure to be seen and controlled is the vital renal pedicle whereas it should be the first. The excessive manipulation required by lumbar nephrectomy has in the past resulted in the operative rupture of one-third of these tumors. This immediately makes the prognosis practically hopeless. Furthermore in many of the extra peritoneal nephrectomies, the peritoneal cavity is opened more or less widely although unintentionally thus immediately cancelling one of the benefits of this particular approach. Our records of operative mortality and end results show that, even when dealing with small tumors, lumbar nephrectomy has fallen far short of the objects we seek.

Fortunately it is not the only procedure at our disposal. The alternate operation is transperitoneal nephrectomy.

The advantages of transperitoneal nephrectomy. These are definite. In the first place the generous abdominal incision enables one to see the tumor clearly and to expose and ligate the renal vessels before one handles or moves the malignant mass. Aberrant vessels can be controlled because one can see the entire flank. Furthermore, the exposure allows one to remove not only the mass and the kidney intact, but also the surrounding tissues, the capsule of Gerota, the perirenal fat and areolar tissue and as much of the ureter as one wishes. In theory therefore the operation is based on sound principles of surgery and pathology.

Furthermore, these principles are not new or radical. They have been advocated for many years. In 1905 Walker recommended transperitoneal ligation of the renal pedicle as the first step preliminary to nephrectomy by the lumbar

route. At that time he stated that he had never seen or heard of transperitoneal nephrectomy. Nine years later, in 1914 J M T Finney deliberately planned and performed transperitoneal nephrectomy for a small hypernephroma and the patient is well today. In 1921 Quinby stated that tumors of the kidney should be removed transperitoneally although he described a surgical technique which we believe to be unnecessarily complicated and which we shall discuss later. We do not know whether he still uses that technique. Most of the recent textbooks on general surgery state without reservation that renal tumors should be removed transperitoneally.

In view of the widespread approval of the principle of transperitoneal nephrectomy and in view of the known shortcomings of lumbar nephrectomy, there must be some very real explanation for the fact that lumbar nephrectomy continues to be the method which is most commonly used.

The chief reason is probably the question of operative technique. Although transperitoneal nephrectomy is recommended in practically all modern surgical texts it is described in very few of them, and in none is there an illustration which would in any way help one to visualize the steps of the operation. Furthermore, the technique which is often recommended is unnecessarily complicated and presupposes an anatomical familiarity with the upper abdomen which is possessed by practically no urologists, very few gynecologists and not all general surgeons. The method often recommended involves the identification and mobilization of the duodenum, the jejunum or the ligament of Treitz, and eventually by the use of these landmarks the localization and ligation of the renal pedicle. Most of the renal surgery in this country is done by urologists and gynecologists, and to men in these specialties the upper abdomen is rather unfamiliar ground. Obviously, an operation thus designed could never be generally adopted. Indeed it would be hazardous for the average gynecologist or urologist to attempt it. Realizing this unsatisfactory state of affairs, when Kelly and Burnam wrote their classic two volume text on *Diseases of the Kidneys, Ureters and Bladder* in 1915 they dismissed the whole subject of transperitoneal nephrectomy in one short paragraph, condemning the procedure unceremoniously. We hold the same opinion of the highly complicated operations that are often recommended. As we shall show however these technical complications are entirely needless because transperitoneal nephrectomy can be made a very simple and safe operation.

Fig. 3 The exposure of the renal pedicle. The mobilization of the peritoneum carries out of the operative field the colon and duodenum and brings one directly to the vena cava and the renal vessels. The artist does not exaggerate the clearness of the view. By this technique one obtains complete control of the blood supply of the renal neoplasm with very little manipulation. It may not be necessary to expose the vena cava. With such exposure one can devote his attention to the removal of the tumor with a wide margin of surrounding tissue, the control of the blood supply is usually a simple problem. One can also remove as much of the ureter as is necessary.

Less valid is the objection that the operation involves opening the peritoneal cavity. If, in this instance we had the choice between two equally satisfactory operations, one extraperitoneal and the other intraperitoneal it would certainly be good judgment to use the extraperitoneal route. But in this case the extraperitoneal approach is fundamentally faulty whereas the transperitoneal route gives us at least an opportunity to handle the surgical problem in a safe and scientific manner. The experienced surgeon would much prefer a wide transperitoneal view of a dangerous situation to a cramped extraperitoneal peep at it.

We do not underestimate the fact that a transperitoneal operation introduces factors which one need not consider when the peritoneum is not opened. We dismiss the question of peritonitis because we do not recommend this operation for infected kidneys, except in rare situations. For the transperitoneal operation, however, the

One can waste a great deal of time and increase the surgical shock by trying to pack away the intestines before relaxation is complete.

Step 2 The exposure of the tumor As the illustrations show the operator works directly across the peritoneal cavity. The hyperextension of the back however, brings the lumbar wall nearer to the surface, and the big incision makes it entirely unnecessary to work in a hole. In fact one should feel a distinct sense of roominess which gives one confidence and ease.

After the intestines have been pushed into the opposite half of the abdomen one is brought immediately to the posterior abdominal wall. The large intestine is seen coursing vertically and in the renal fossa one sees the bulging caused by the kidney mass. These are the landmarks.

Step 3 The layer of posterior peritoneum is now incised. This is also a very simple step. The incision in the posterior peritoneum should be made at least 2.5 centimeters from the lateral margin of the large bowel so that one will not injure it and have a wide flap of peritoneum for easy approximation afterward.

I find that it is much easier to incise this layer of peritoneum if one mobilizes it before cutting it. One picks up the peritoneum at a clear spot nicks it with a knife and then by inserting the closed scissors into this opening mobilizes the peritoneum in the line of the desired incision. This step is illustrated.

The peritoneum is thus mobilized and cut well above the flexure of the large intestine. The large intestine is then gently pushed medially and held back by the gauze and retractors which are already in place. The peritoneum is also pushed away from the region of the renal pedicle and the kidney. The duodenum goes with the peritoneum and ascending colon. If by chance the kidney tumor and the peritoneum are intimately adherent one can leave a wide patch of peritoneum on the kidney and remove it with the tumor. When operating upon the left kidney one does not have to think of the duodenum.

The elevation of the posterior peritoneum brings one down directly to the retroperitoneal mass. The kidney is usually visible. The renal pedicle and pelvis are hidden under a layer of loose fat. In thin persons, the ureter can often be seen. It can almost always be picked up by rolling the loose areolar tissue and fat between the fingers. It can thus be exposed easily and if traced upward will lead directly to the renal pedicle. It is often helpful to expose the ureter to the kidney at this stage because this procedure aids in exposing and mobilizing the renal vessels.

Fig. 4. A cross section view of transperitoneal nephrectomy. This shows how completely the large intestine and the duodenum are eliminated from the operative field by this technique. We make it a practice to remove Gerota's perirenal fascia with the tumor.

Step 4 Ligation of the renal pedicle This is the most important step in the whole operation. In order to expose the renal vessels clearly it may often be advantageous to mobilize the lower pole of the kidney. This can be done gently without moving the kidney in its retroperitoneal bed. It is always necessary to push the peritoneum and all other structures away from the region of the renal pedicle before attempting to isolate it. If one follows this simple rule he will never have to fear injuring the duodenum or any other adjacent structure. In all cases, the operator should get a clear view of the renal artery and veins also he will often see the aorta and vena cava as well.

The renal vessels are usually buried or covered by a layer of fat. They can be located in several ways. By palpation one can feel their pulsation. Their relation to the renal hilum usually points them out. Then again the ureter leads directly to the renal pelvis.

As a rule there is no difficulty whatever in locating not only the renal vessels but also aberrant arteries and the ovarian or spermatic vein. Before clamping and controlling the renal artery and veins, it is always wise to expose them thoroughly removing the fat and areolar tissue by which they are concealed. They should be elevated from the bed in which they lie so that a ligature may be passed around them. This procedure is done carefully and under full vision.

Every surgeon will have his own particular method of preference in handling and isolating the renal pedicle and he will probably vary it with changing demands.

Step 5. Removal of the tumor. It is essential that there should be no back bleeding from the tumor or kidney at any time as this blood will probably contain cells of the tumor. Local recurrence is very likely if this occurs.

The removal of the tumor is usually a fairly simple matter after the blood vessels have been ligated and cut. We have not observed any unusual adhesions as the result of pre-operative irradiation. In fact the irradiated tumors are usually harder more compact have a thicker capsule and are definitely less friable and vascular than tumors which are not irradiated. We try to remove all of the perirenal tissue possible, including the perirenal fat, Gerota's capsule (the perirenal fascia) a long strip of the ureter and all the areolar tissue we can safely take away.

Step 6. Closure. The posterior layer of peritoneum is closed tight by a continuous suture of plain catgut. If drainage is necessary it can be provided through a stab wound extraperitoneally in the flank. We did not drain our last two transperitoneal nephrectomies, and the wounds healed cleanly.

The operation which we have described is usually done very easily in a little more than 1 hour, requires no pulling or tugging, entails very little shock, and in our opinion, is much less risky than a lumbar nephrectomy for tumor.

CONCLUSIONS

We have described and illustrated the steps of a simple method of performing transperitoneal nephrectomy. We present this because of the current opinion that transperitoneal nephrectomy is a dangerous and complicated operation and because this particular technique has not been illustrated in the available literature. It is our

opinion and the opinion of many other surgeons that transperitoneal nephrectomy is far safer than lumbar nephrectomy for the removal of renal tumors.

We present this as part of a study of renal tumors. In another communication we outlined our experience with the pre-operative irradiation of malignant renal tumors. We have found that pre-operative irradiation makes many of these big tumors operable by reducing their size remarkably. It has also been our experience that in transperitoneal nephrectomy we have a surgical technique which gives us a chance to remove these tumors with fair safety and with a minimum likelihood of rupturing the mass. We cannot venture an opinion as to the effect this method of treatment will have on the number of permanent cures. We do know however that the first step is the successful removal of the tumor and in this communication we have outlined two procedures which have helped us to accomplish this step.

LYMPHANGIOMATA OF THE GREAT OMENTUM¹

ALBERT H. MONTGOMERY, M.D. AND IRVING J. WOLMAN, M.D. CHICAGO, ILLINOIS

ABDOMINAL tumors are not common in children. The most frequent and generally recognized types at this age are neoplasms involving the kidney and ovary. Among the rarer forms are the lymphangiomas of the great omentum. These tumors occur very infrequently and the cases are somewhat of a surgical and pathological curiosity. Sporadic isolated case reports appear from time to time. Stillman reported 2 cases in 1911, and included in his paper summaries of 19 other cases which had been published up to date. We have verified his sources and reviewed the literature since 1911 with reference to 2 cases recently observed at the Children's Memorial Hospital, and have found reports of 30 other cases including 5 reported before 1911 which were omitted from Stillman's group. The total number of cases, including our own, is 53, a group which is sufficiently large to permit some statistical discussion with a view toward outlining the significant features of the general disease picture.

Our interest in this subject was stimulated by 2 patients who came under our observation with the following case histories:

CASE 1. L. K., a Polish girl, 5 years of age, entered the Children's Memorial Hospital, April 7, 1931. About 3 years previous, the mother had noted that the child's abdomen was gradually becoming larger. During the next 4 months the child seemed rather listless at home, played very little and had a poor appetite, but did not complain of any pain. The abdominal swelling seemed to fluctuate a little in size during this period. For the next 16 months up to the time of admission, the child's condition had been rather stationary with no change in the size of the abdominal tumor or in the listless appearance of the child. However about 5 weeks before her entrance into the hospital she began to complain of abdominal pain occurring mostly at night and causing her to cry out. There was no nausea during this period, but her mother thought that occasionally the child showed a small amount of fever.

During the two previous years she had had chicken-pox, whooping cough and measles without complications. Her history otherwise was negative.

The findings on physical examination showed nothing abnormal except the abdomen which was quite prominent and had a doughy resistance but seemed to be tympanitic throughout. In the right lower quadrant in the region of McBurney's point a discrete, movable mass about the size of an egg could be palpated. It was not tender and could be moved around for a distance of about 3 inches. The mass felt distinctly like a cystic tumor.

An examination of the urine showed nothing abnormal, and a tuberculin skin test was negative. An examination of the blood showed hemoglobin of 55 per cent, red blood cells 3,360,000, and white cells 11,400 of which 50 per cent

were polymorphonuclear leucocytes and 48 per cent lymphocytes.

During her period of observation the child developed scarlet fever complicated by the finding of diphtheria organisms in her throat during convalescence. It was necessary to remove the child's tonsils before a negative throat culture could be obtained. After that the child seemed to be in good condition so it was decided to investigate the tumor mass in the abdomen by means of an exploratory laparotomy.

Operation. July 18, 1931, under ether anesthesia the abdomen was opened by a midline incision. It was found that the mass that had been palpated before operation, was attached to and part of a large cystic tumor which occupied most of the great omentum. The mass was easily delivered from the abdomen except for the part which was attached to the transverse colon near the splenic flexure by a broad pedicle. This was severed as close as possible to the colon and the tumor removed. For fear of interfering with the blood supply of the colon, a few small cysts were left in the pedicle when it was ligated. The abdomen was closed and the child went on to an uneventful recovery. She was discharged from the hospital in good condition on August 2, 1931.

Pathological examination. Report by Dr. Irving J. Wolman (Fig. 1). The specimen is a large irregular tumor mass weighing about 1,500 grams and measuring 30 by 30 by 8 centimeters when completely spread out. It consists of numerous confluent rounded cysts situated within the substance of the great omentum. The cysts vary in size from being just visible up to 13 by 9 by 6 centimeters which is the measurement of the largest. The cysts have rounded contour and many are spherical, others seem to have anastomosed and their shape is more irregular. There are numerous constrictions and grooves on their surfaces. Sometimes they seem to anastomose with each other through a cluster of smaller intermediate lying cysts. Their wall is thin and pale, often membranous, and shows dilated narrow widely separated blood vessels within it. The outer surface has a smooth, serous appearance. Strands of delicate omental fatty areolar tissue run among the nodules binding them together. The cyst content consists of colorless or gray semi-solid jelly like fluid. It varies in consistency and opacity in the various chambers. After preservation in formaldehyde these contents assume a white coagulated appearance. In several cysts, the capsule is thick white, and hyaline, measuring as much as 2 millimeters in thickness. The lining is pale and smooth, but there are patches of coarse, wrinkling and elevated trabeculations. No blood or large cellular masses are noted within the cysts. They extend all through the omentum some being present at the cut edge. The gross appearance is that of a cystic lymphangioma of the omentum.

Histological note (Fig. 2). Five sections were examined. The cyst contents stain a homogeneous pale granular matter. Their walls are formed of hyaline, relatively acellular fibrous tissue in the form of a capsule. The wall of some cysts is more compact and thicker than others. Occasional small round cells occurring singly or in small groups are noted within the interstices, and also some large mononuclear cells with basophilic homogeneous cytoplasm and eccentric hyperchromatic nuclei. There is no

Fig. 3 Unilocular cystic lymphangioma of the great omentum

TABLE I—AGE OF PATIENTS AT ONSET OF SYMPTOMS

	Cases
Infancy	11
to 5 years	18
6 to 10 years	5
"Child"	1
10-20	5
20-30	5
31-40	2
41-50	3
51-60	0
"Adult"	3
Patients under 10 years	35
Patients over 10 years	8

It is noticeable that 35 or approximately 66 per cent, of the cases were in children under 11 years of age. In regard to the character of the lymphangiomata, 25 were unilocular, 25 multilocular, and in only 3 cases were multiple tumors present.

The cyst in most cases rested entirely free in the abdominal cavity except for the pedicle attachment. In 15 cases adhesions were found between the cyst and other structures in 6 instances to the abdominal wall in 6 to the uterus and in 1 to the intestine, pancreas, and inguinal canal, respectively. The tumors graded in size from the very smallest to cysts that were recorded as containing 16 quarts or weighing from 40 to 60 pounds.

The most frequent pathological complication was twisting of the pedicle of the cyst that occurred in 6 cases. Rupture of the cyst occurred in 1 case and hemorrhage into the cyst in another.

The clinical features associated with these lymphangiomata are not characteristic. Symptoms are usually slow in developing and are of long duration, the average time being 2.3 years. In a general way these cases may be grouped clinically as shown in Table II.

TABLE II—CLINICAL FEATURES OF LYMPHANGIOMATA OF THE GREAT OMENTUM

	Cases
Group 1—Symptoms due to the size of the tumor	42
A—Diffuse abdominal swelling	31
B—Localized palpable mass	9
C—Abdominal pain and distress	11
Group 2—Symptoms produced by twisting of pedicle or rupture of cyst. Clinical picture closely simulates that of appendicitis or twist of pedicle of an ovarian cyst	6
Group 3—No symptoms—Cyst discovered incidentally during abdominal operation	5

1. In the first group symptoms are due to the size of the tumor. A very large majority of the cases in this series, 42 of 53, were in this group. The most frequent clinical finding in these patients was a diffuse abdominal swelling which was present in 31. The swelling in many instances showed signs of fluid which appeared to be cystic in some cases, but was regarded as ascitic in others. The principal symptoms associated with the abdominal swellings, when they become large, were general weakness which was evident in 5 patients, dyspnea on exercise which was exhibited by 6 patients, and loss of weight which occurred in 4 patients.

Instead of a diffuse abdominal swelling a palpable local lump was present in 9 cases. In our first case, the size of the palpable mass gave a very erroneous idea of the actual size of the cystic mass. Sensory symptoms were noticeably absent in most cases in this group, but abdominal pain and distress were described by 11 patients. The pain was usually of a dull character and was present at irregular periods. Loss of appetite with or without nausea and vomiting was not infrequent.

2. The second group, in which the symptoms were produced by a twisting of the pedicle of the cyst consisted of only 6 cases. In contrast to the larger previous group the clinical features were all indicative of an acute abdominal inflammation resembling appendicitis, or the torsion of the pedicle of an ovarian cyst.

The clinical picture usually began with abdominal pain associated with nausea and vomiting. Abdominal tenderness, and sometimes rigidity with moderate fever and leucocytosis were present. In one of the cases of this group the symptoms were due to a traumatic rupture of the cyst.

3. The third group was made up of 5 cases in which there were no symptoms and the cysts were discovered incidentally during operation for other abdominal conditions, usually uterine myomata.

The indefinite and meager clinical features and the rarity of these omental cysts tend to make the diagnosis somewhat difficult. It is not strange therefore, that in this group of 53 cases the correct pre-operative diagnosis was made in only 1 instance. A diagnostic abdominal puncture was made in 13 cases, but it did not seem to be of much assistance. It was employed in our second case and the finding of bloody fluid only served to obscure the diagnosis. The fact that 66 per cent of the cases reported have been in the age of childhood should be emphasized, as well as the comparatively symptomless character of the slow growing abdominal mass.

Tuberculous peritonitis will often be confusing unless it can be ruled out by a negative tuberculin reaction. Ovarian cysts which are not confined to the pelvis will be hard to differentiate. Mesenteric cysts, uterine myomata and congenital cysts of the liver will have to be considered. The cases with acute symptoms due to a twisted pedicle simulate appendicitis or torsion of an ovarian cyst so closely that differentiation will probably be impossible.

Surgical treatment was employed in all of the cases in this series except the first one on record which was reported in 1851 by Gairdner who found an omental cyst at autopsy. Aside from the fact that some of the patients are very young the operative procedure is relatively simple. The cyst is exposed, freed from adhesions, and removed in the same manner as an ovarian cyst.

The surgical results in general were very satisfactory. Omental cysts are benign tumors and do not tend to recur after removal. The operative mortality in this series was very low as there were only 2 deaths in the 53 cases.

SUMMARY OF CASES COLLECTED FROM THE LITERATURE

In 1911 Stillman reported 2 cases of true lymphatic cysts of the omentum and collected 19 others from the literature. These included the unilocular solitary type of cyst as well as the multilocular lymphangiomas, and were reported by Gairdner (1851) Gooding (1887), Spencer Wells (1890) Erdheim (1896), Marian (1896), Hearn (1897) Braithwaite (1898) Jacobi (1901), Marsh and Monsarratt (1901), Schramm (1903), Boyd (1903), Schwarzenberger (1894) Young (1905) Matthews (1905) Fort (1907) Wakefield (1907) Rodman (1909) Seefisch (1909) and Gifford (1910). Details concerning the above tumors are readily available in Stillman's comprehensive article. We have reviewed the more recent literature to supplement the above list

and we have found reports of 30 more cases, not including the 2 cases of our own. The 30 cases abstracted are as follows

CASE 22. Reported by Brandt. Patient was 15 years of age sex not stated. The patient had a freely movable abdominal tumor reaching to the navel, and the diagnosis of omental cyst was made. Operation disclosed a large, single cyst containing 2 liters of dark fluid. The wall was not lined with endothelium. Recovery was uneventful.

CASE 23. Reported by Dewitsky and Morosow. In a male, 3 years of age, an abdominal swelling was noted in the first year of life. Physical examination showed an enlarged abdomen with circumscription at navel of 64 centimeters and a fluid wave and dullness to percussion. There had been an intermittent diarrhea since 1 month of age. The clinical diagnosis of tuberculous peritonitis was made. Operation exposed a large abdominal cyst containing 4 liters of chocolate colored fluid which was evacuated. Repair of a congenital inguinal hernia was also done. Death occurred the next day. At autopsy the large cyst and numerous smaller cysts were found to have an endothelial lining, the omental lymphatics were dilated.

CASE 24. Reported by Da Costa. A thin walled unilocular cyst containing dark colored fluid and having a fibrous lining was removed from a male child.

CASE 25. Reported by E. M. Hasbrouck. The patient, 50 years of age, colored, had an abdominal swelling which had begun 1 year previously and gradually increased until the abdomen became enormous. Dyspnea, constipation, and frequent micturition resulted. At operation a large, thick walled cyst containing a blood clot, and with many small cysts in its wall, was found. This was estimated to weigh about 40 pounds. It was situated in the omentum between the stomach and transverse colon. Microscopically the cells appeared epithelium like in structure with a disposition to arrange themselves in columns encircling the blood vessels. Hasbrouck considered the specimen to be an endothelioma. However, it was later restudied in the laboratory of Dr. J. C. Bloodgood (according to McDonald) and was there considered a benign lymphogenous cyst.

CASE 26. Reported by N. M. Kakuschkin. The patient, a female, 28 years of age, had a history of gonorrhea. An abdominal tumor had been noted for 5 months. A pre-operative diagnosis of omental or ovarian cyst was made. Operation showed many small cysts in the omentum, which was bound to the internal genitalia by numerous fibrous adhesions. These cysts were lined with flat mesothelial cells, which occasionally assumed a cuboidal appearance. Evidences of hemorrhage were found in a few of the chambers.

CASE 27. Reported by Markoe and McPherson. Female adult. In the course of a hospital stay for purposes of confinement, an easily movable, painless tumor was palpated just above the fundus of the uterus, between the ensiform cartilage and umbilicus. After delivery a second tender fixed mass was palpated in the left broad ligament region. At operation two separate and distinct cysts were removed from the omentum. The larger, the size of a grapefruit, lay in the right side of the pelvis, displacing and adherent to the uterus. The other, the size of an orange, was adherent to the appendix. The cysts were filled with serous fluid, had smooth fibrous walls, and were subdivided by connective tissue septa. No endothelial or epithelial lining was recognizable. Certain areas had undergone calcareous degeneration.

CASE 28. Reported by Markoe and McPherson. Female, 27 years of age. A tumor in the right inguinal region had

been present since birth. This was found to be the size of a grapefruit, slightly fluctuant, and gave no impulse on coughing. It was thought to be an inguinal hernia. On cutting down over the mass the operator found it to be a thin walled omental cyst which had prolapsed through the inguinal canal and was attached by a long pedicle. Through an abdominal incision the pedicle was tied off and the cyst was easily removed by way of the inguinal incision. Recovery was uneventful. The cyst wall was found composed of connective tissue principally with some round cell infiltration indicating acute inflammation.

CASE 29. Reported by Frank. Female, 30 years of age. The patient had been wearing a pessary for 10 months because of uterine prolapse. Seven months ago she noticed an enlargement in the pelvis which had been gradually increasing in size. Her bowels were constipated. On examination a cystic abdominal tumor was palpable in the region of the navel, and there was a protrusion of the abdomen about the size of two fists. Per vaginam a number of cystic nodules could be felt, filling up the entire pelvis. A diagnosis of ovarian cystomata was made.

At operation a large multilocular cystic formation of the omentum was removed. In addition, numerous small similar cysts were scattered on all the peritoneal surfaces, the caecum, small gut, mesentery, uterus, broad ligament, tubes, and ovaries. Each cyst was easily separated from its neighbor and from its attachments. Their walls were thin and they contained clear serum. A rather large cyst was found in the groin fascia, external to the external inguinal ring. All the cysts had an identical microscopic appearance, and were lymphangiomatous in character.

CASE 30. Reported by Funk. Female, aged 7 years. An abdominal swelling was first noted 3 years earlier. The abdomen became the size of a 9 months pregnancy and produced symptoms on pressure. Operation showed a single, large cyst within the substance of the omentum, which was distended and then dissected. Its wall was thin, regular in thickness, and consisted of fibrous tissue. Internal to this capsule was a single row of flat cells. Recovery was uneventful.

CASE 31. Reported by Outebridge. Female 34 years of age, had a large uterine myoma, with many adhesions in pelvis. There were numerous endothelium lined, numerous small grape like cysts filled with clear fluid. The omental margin, with a string of smaller ones running down the center. There was a continuous gradation from the simple dilated lymphatic channels to the largest cyst. The author believed that the per uterine adhesions blocked the lymphatic circulation and thus produced this lymphangiomatous dilatation.

CASE 32. Reported by Kenney and Mason. Female 30 years of age, had had abdominal discomfort for 6 years and swelling for 3 years. No pre operative diagnosis was made. A large multilocular cystic lymphangioma of the omentum was found. Some adhesions to the parietal peritoneum were present.

CASE 33. Reported by Bloodgood. Female, aged 3 years. This infant had had swelling of the abdomen for 3 months. An exploratory operation was done and a cyst in the lesser peritoneal cavity was opened and drained. The patient recovered and was well 1 year later.

CASE 34. Reported by Bloodgood. Male, aged 5 years. There had been intermittent attacks of abdominal pain for 18 months, with nausea and vomiting. Swelling of the abdomen, resembling ascites, was also present increasing rapidly during the last 6 weeks. Aspiration yielded 3 quarts of reddish fluid. At operation a large multilocular single cyst was found and removed. Twelve days later a second operation had to be done because the ligated omental stump had become gangrenous.

CASE 35. Reported by Bloodgood. A child, 4 years of age, had a large, single lymph cyst measuring 27 by 20 by 10 centimeters removed from the omentum. In its wall other minute cysts were found. The child was well 1 year later. No clinical data is given.

CASE 36. Reported by Pylkes. Female, 4 years of age. The abdomen was swollen since 9 months of age. It was tapped when she was 18 months, 3 years, and 4 years of age. Slightly red fluid, containing cholesterin crystals was obtained. Operation showed a thin walled cyst occupying larger part of abdomen. It was partially loculated and situated in the greater omentum, from which it was readily stripped. The upper part peeled from greater curvature of stomach. The omentum was repaired after removal, completing the anterior wall of the lesser sac. Recovery was satisfactory and the child was discharged in a week. The cyst was the size of a large soccer ball. Microscopic examination showed no epithelial lining to its wall.

CASE 37. Reported by Speese. Male, 5 years of age had a sudden abdominal pain 24 hours before admission. There had been no previous symptoms. The abdomen was found distended with some tenderness and rigidity over appendiceal region. The white blood count was 20,000 with 80 per cent polymorphonuclear cells. A diagnosis of acute appendicitis was made. At operation an omental cyst containing 35 cubic centimeters of amber fluid with pedicle twisted was found in the upper right abdominal quadrant. The cyst was removed. Death from anoxia occurred the next day. At autopsy numerous small clear cysts were found in the gastrosplenic and greater omentum. The cyst walls were lined with endothelium. Some of the omental lymphatics were dilated.

CASE 38. Reported by Halsted. Female, 2 years of age. The child had a swollen abdomen and the diagnosis of ascites was made. When a small incision for drainage of the abdomen was made, the delicate cyst wall presented itself and commenced to herniate. On further exploration a large thin walled hygrota and several smaller ones were discovered in the greater omentum and posterior mesogastrium. These were opened and drained. When the patient was seen at 24 years of age, she was normal, and there was no suggestion of an abdominal tumor.

CASE 39. Reported by Boncher. Male 43 years of age. Abdominal enlargement had been present since May, 1918, no other symptoms. Operation was advised when the patient was first seen in October, 1918, and refused. When brought back February, 1919, the child had an enormous abdomen hanging like a bag. He had to sit with legs wide apart to make room for belly. The abdominal circumference was 74 centimeters or 34 inches. Abdominal puncture yielded a small amount of brownish, albuminous liquid. The physical examination otherwise was negative, and the von Perquet test was negative. The diagnosis of ascites of unknown origin or "cystic tumor" was made. At operation a multilocular omental tumor was easily removed. Convalescence was uneventful and the child as well when seen 3 months later. The entire omentum was filled with cysts of all sizes, up to an infant head. These were supported by thick, fibrous, trabeculated septa, many intercommunications. They contained brownish shrunken albuminous fluid, which formed a sediment of fatty cells, lymphocytes, cholesterin crystals, and debris. The walls were made of dense, nuclear connective tissue, in which were many thin-walled dilated vessels. Some of the cavities were lined with endothelium. There were many lymphocytes in the supporting stroma and a loose network of smooth muscle fibers.

CASE 40. Reported by Gurvin. Female, 30 years of age. The patient was operated on for a uterine fibroid, which was found to be a twisted pedicle attached to and sur-

whed by the omentum. They found many lymphangiectatic cysts on the right side of the omentum and ascribed the cysts to blocking of the lymphatics.

CASE 41. Reported by Arsela. Female, 3 years of age. Gradual swelling of the abdomen began at 1 year of age. She was brought to the hospital for frequency of vomiting of 3 days duration. The abdomen was uniformly enlarged, smooth, fluctuant, and dull to percussion. The diagnosis of omental or mesenteric cysts was made. At operation a pedunculated cyst measuring 17 by 26 centimeters was discovered arising by a pedicle from the central region of the greater omentum. It was removed without difficulty and the child made an uneventful recovery. The tumor had a thin, transparent wall and contained clear lemon colored watery fluid. It was lined by flattened mesothelial cells. Many blood and lymph capillaries and clumps of lymphocytes were found in the wall, but no other cysts. The author attributed the cystic formation to an anomalous development of a lymph node.

CASE 42. Reported by Bernadet. Male, 24 years of age. The patient had had an abdominal tumor for 5 months, which suddenly became painful and caused vomiting. At operation a cyst the size of an apple, with twisted pedicle was found. The specimen was not described further.

CASE 43. Reported by Lawrence. Female, 3 years of age. The abdomen had been prominent since birth. There had been frequent attacks of abdominal pain for 6 months, relieved by cathartics 24 hours before admission to the hospital. She was taken ill with severe abdominal cramps. There was no vomiting and enemas gave no relief. When examined, she appeared prostrated, with a distended abdomen which was tense, smooth, dull to percussion, and cyanotic in color. There was a leucocytosis of 12,000 cells, with 82 per cent polymorphonuclears. At operation a large omental cyst with a twisted pedicle was found and removed. Convalescence was satisfactory. The cyst had several large communicating compartments, and was lined with endothelium.

CASE 44. Reported by Ladd. Female, 8 years of age. She had had for 3 months a distended abdomen which was flat to percussion and presented a fluid wave. Examination was otherwise negative except for undernutrition. Exploratory puncture yielded a brownish cloudy fluid containing broken down red cells. At operation a large thin walled cyst was removed from the great omentum, close to the transverse colon. This contained over 1,000 cubic centimeters of fluid. Microscopic examination showed the wall to be composed of alternate layers of smooth muscle and connective tissue. It was quite vascular and aggregations of lymphoid cells were seen about the blood vessels. The pathological diagnosis was omental cyst of lymphatic origin. Convalescence was uneventful.

CASE 45. Reported by Ladd. Female, 8 years of age. The patient had been losing weight for several months. When first seen, she complained of distended abdomen, headache, malaise and joint and muscle pain of 5 days duration. There had been no vomiting. Her white blood count was 10,500. There was found a large tumor mass on the right side of the abdomen which shifted to the hypogastric region. Cystoscopic examination was negative. At operation a large cyst measuring 13 by 8 by 6 centimeters was removed from the omentum. Its pedicle was twisted. Recovery was satisfactory. Microscopic examination showed a fibrous wall with a few strands of smooth muscle within it, and also some aggregations of lymphocytes. There was no epithelial lining. The pathological diagnosis was omental cyst of lymphatic origin.

CASE 46. Reported by Ryan. Male, 4 years of age. The abdomen had been large since birth, and was tapped at 2 years of age when a large amount of brown fluid was

removed. The swelling recurred again and respiratory embarrassment appeared. A smooth doughy mass was palpable in the upper mid-abdomen. Operation showed a multilocular cyst of the great omentum, forming a group of nine endothelium lined cysts with many small, round fibrotic masses in their walls. Convalescence was uneventful.

CASE 47. Reported by Rau. Male, 24 years of age. A tumor in the left hypochondrium the size of a marble was first noted 7 months earlier. This had grown rapidly to the size of an orange. Hematuria was also present for 3 months. The operation showed a cyst in folds of the great omentum which was easily peeled out. The tumor was 5 inches in diameter and contained white, milky fluid, its lining was thin and shiny. Recovery was uneventful. The blood disappeared permanently from urine 5 days after operation. No microscopic report was made.

CASE 48. Reported by Howe. Male infant aged 2 years. The patient had had a left inguinal hernia since 6 weeks of age. At age of 1½ years, this became irreducible and 3 weeks later was operated on. Before operation the tumor in the groin was the size of a small coconut, fluctuant and translucent. It could be partially reduced. The diagnosis of hydrocele was made. At hernial operation a large, single cyst with 30 ounces of clear dark yellow fluid was removed. This had one small diverticulum. No microscopic description was given.

CASE 49. Reported by Grausman and Jaffe. Male, 44 years of age. For several months, the patient had right lower abdominal pain with indefinite abdominal symptoms. On examination there was found diffuse abdominal tenderness, and a white cell count of 14,000 with 86 per cent of polymorphonuclear cells. At operation a large cystic omentum was found and removed. Hundreds of cysts varying from 1 millimeter to 1 centimeter in diameter were present. These were endothelium lined and contained clear fluid. The omental lymphatics were dilated and lymphoid cell infiltration with follicle formation had occurred. Recovery was uneventful.

CASE 50. Reported by Fisher. Male, 4 years of age. Abdominal pain and distress were present for 3 days. Examination revealed a large fluctuant abdomen with numerous dilated veins, a hard mass in the upper left quadrant with pain felt on pressure and reflected to the left inguinal region and causing marked flexure of both thighs. The white blood count was 13,050 with 75 per cent polymorphonuclears. Temperature was 100 degrees. At operation a large multilocular cyst and several smaller ones were found within the omentum. The entire omentum was removed. It weighed 13 pounds. Convalescence was uneventful, and there was no evidence of recurrence 1 year later. Microscopic examination showed the cysts to have a lining of flattened endothelium in addition many cavernous lymph spaces ramified through the omentum.

CASE 51. Reported by Wyzatt in *Minnesota Med.* 1931, 14: 656. Female, aged 3½ years. For 2 days child had had symptoms of acute appendicitis with fever, vomiting, abdominal pain and rigidity. At operation 1,000 cubic centimeters of green fluid was found in the abdomen. A large multilocular cyst in the great omentum measured 5 by 3 by 5 centimeters. One large chamber had ruptured. Microscopically the cysts had an endothelial lining.

SUMMARY

Two cases of lymphangiomas of the omentum are reported in detail and 51 were found in a careful survey of the literature up to date.

These tumors are true neoplasms and about two-thirds of them have occurred in children.

The symptoms produced by these tumors are due either to their size or to twisted pedicles.

They can be permanently removed by simple surgical treatment with little risk to the patient.

BRANCHIAL CARCINOMA

LATERAL CERVICAL NEOPLASM

GEORGE CRILE MD FACS AND J. E. KEARNS JR MD CLEVELAND OHIO
Cleveland Clinic

THE fact that less than 100 cases of branchiogenic carcinoma have been reported in the literature, and that the largest single series that we have been able to discover is that reported by Lorenz, who reports but 8 cases, makes it appear that it would be of interest to present our observations in a series of 28 cases seen by one of us at Lakeside Hospital and at the Cleveland Clinic. Although branchial carcinoma is among the most malignant lesions and the disease is usually fatal nevertheless, it is well to accumulate experience in the treatment of the lesion in order to find what therapeutic methods offer the best chance of relief or of temporary cure.

Branchial carcinoma was probably first described by von Volkman, in 1882 as a tumor of the neck for which no source could be found in the skin lymph glands, nose mouth pharynx ears or esophagus. (Essentially the same factors are present in the diagnosis today.) Hudson presented a series of 6 cases of so called branchial carcinoma in which 5 came to autopsy and revealed other sources to account for the lesion. However in view of all the evidence available today such a pathological entity surely exists although its exact mode of origin is obscure.

CLINICAL PICTURE

The total number of cases of branchial carcinoma in our series is 28 all of which were studied pathologically and were definitely diagnosed. Autopsy in 1 case disclosed no other site of malignant change. For comparison with the data on malignant branchial lesions 70 cases of benign cysts have also been studied and presented in a few of the tables. Our results closely approximate those of Shedden.

The age of occurrence of lateral cervical carcinoma, as is the case with most carcinomatous lesions falls in the latter decades of life. Two-thirds of the patients in this series had attained the age of 50 years while nine-tenths were more than 40 years of age. The oldest patient was aged 80 years and the youngest was a man aged 37 years. Comparisons between the ages of occurrence of benign and malignant lesions in our series are shown in Table I and Figure 1.

Branchiogenic carcinoma seems to occur more frequently in men than in women but no relation

ship between incidence and the occupation of the patient could be demonstrated. There is approximately an equal distribution of lesions between the two sides of the neck, but bilateral occurrence was noted once in our series. The growth of the malignant tumors is rather rapid as compared with those of a benign nature. In the case of the malignant tumors, the longest period before the patient appeared for treatment was 3 years with an average of about 7 months while in the case of the cystic lesions the longest period before the patient presented himself for treatment was over 4 years. Nine tenths of the patients with branchial carcinoma reported the speed of the growth as rapid, while only one third of those with cysts showed rapid increase in size which is seen chiefly in the younger patients (Tables II and III).

The site of branchial carcinoma is usually high in the neck below the angle of the jaw or in close proximity to the ear near the sternocleidomastoid muscle (Fig 2). Only one patient in this group had a lesion close to the clavicle (Fig 3). The occurrence of pain is fairly frequent and this is referred to the side of the face back of the head, shoulder, base of the tongue, and down the arm on the affected side. In the early stages the pain usually is intermittent, but, because of the close proximity of the growth to the nerves and their early involvement, the pain soon becomes quite severe and continuous. In some cases there was a specific involvement of the seventh, eighth, and ninth nerves and in 1 case a definite Horner's syndrome was present, due, of course to the involvement of the cervical sympathetic system. Three-fourths of the patients with carcinoma complained of pain while only one tenth of the patients with cystic lesions had this symptom (Table IV).

Malignant branchial tumors do not have a constant size, but usually average about 3 to 4 centimeters in diameter and are very firm in consistency unless degeneration has occurred, or a cyst is also present. Usually the tumor is not fixed to the skin unless some manipulation has preceded the examination, but it is very firmly attached to the underlying structures. In the differential diagnosis it is of interest to know that the cystic lesions are seldom attached to the underlying

Fig. 1 Comparison of age incidence of benign and malignant branchial tumors in our series of cases.

structures, and never to the skin unless they have become secondarily infected and break through.

When patients with branchial carcinoma are first seen, they usually are enjoying fairly good health. About 25 per cent showed some weight loss, and 30 per cent had a definite anemia. The previous health is seemingly irrelevant as most patients do not even report any previous upper respiratory infection, and in only 1 case could the presence of tuberculosis be demonstrated in the pathological tissue removed. A positive Wassermann reaction was found in 1 case.

Of the patients in the series who had an ear, nose, and throat examination, in only 2 was it felt that lesions which might possibly account for

Fig. 2 Lateral branchial tumor in a patient 58 years of age; duration of tumor growth 2 months. This is a typical location and shows the very rapid growth that may occur.

the tumor as a metastatic growth were demonstrable. In 1 of these cases it was thought that there was a carcinoma of the larynx, but at necropsy the growth proved to be a direct extension of the branchial carcinoma in the pyriform sinus. In the other case there was a demonstrable mass in the posterior nasopharynx, but on removal of the tumor in the neck a typical pathological lesion could be seen in a cyst wall.

In 11 of the cases in our series roentgenograms of the chest were made and in 3 definite metastases were evident. In 2 cases there were palpable inguinal and axillary lymph nodes. Roentgen examination of the skull jaw and craphagus in several cases demonstrated no pathological change.

The family history is of no importance as only one patient in the group reported the occurrence of cancer in the family.

DIAGNOSIS

In making the differential diagnosis, all tumors of the neck, including mixed tumors, must be considered. Among the more common of these conditions is tuberculosis of the cervical glands, especially when some degenerative process is present. Usually tuberculosis occurs earlier in life than does branchial carcinoma, and there are many nodules rather than a solitary tumor. Leucemia and Hodgkin's disease may be differentiated by blood counts. The diagnosis of a lipoma when it lies above the fascia is readily made, but when the tumor lies deep, the diagnosis is quite difficult and often the nature of the growth can not be determined until the neck is incised.

TABLE 1—AGE INCIDENCE OF BRANCHIAL LESIONS

Age in years	Benign		Malignant	
	Cases	Per cent	Cases	Per cent
or under	8	25		
31-40	5	25		25
51-60		19	14	30
Over 70				5
Unaggreg.	Newborns		27 cases	
A group	89 cases		25 cases	
Older	66 cases		20 years	

Metastatic lesions may occur in the jugulodigastric glands from the ear nose or throat, and it should be borne in mind that in chronic retropharyngeal abscess these glands become quite firm hard and tender and lymphosarcoma also must be ruled out.

Thyroglossal cysts and adenomata of the thyroid gland must be differentiated, but these usually lie in the midline. A few of the rarer lesions such as aneurism deep seated hemangioma, cystic hygroma, and solitary lymph cyst must be considered but most of these conditions must be treated surgically so a definite diagnosis is not essential before operation. It should be remembered that aspiration of a branchial cyst yields a typical fluid.

TREATMENT

The only available methods of treatment of branchial carcinoma are radiation with radium or the X ray or both, and radical removal.

Dr U V Portmann feels that radium can not be used in adequate doses without causing a sloughing of the great vessels which are in such intimate relation with the tumor. The tumor is resistant to roentgen therapy but this is administered to help relieve the pain. Portmann makes an attempt to keep the tissues saturated with the radiation for a considerable period of time. Short wave lengths should be used and a full erythema dose administered for one course of treatment which may be repeated once if necessary. Since branchial carcinoma is highly resistant to radiation roentgen treatment is purely palliative.

The method of treatment employed in most of our cases has been a combination of surgery and X ray. The pre-operative care of the patient is of little consequence except for the possibility of radiation before the procedure and in cases of profound anemia the use of blood transfusion especially in elderly patients. Nitrous oxide anesthesia should be employed. Local anesthesia should be avoided as there is the possibility that infiltration into the area may spread the malignant cells.

OPERATION

In the removal of branchial carcinoma the incision should be made over the tumor parallel to the ramus of the jaw the middle of the incision being over the tumor. At this point when necessary a cut may be made parallel to the sternocleidomastoid muscle which should be long enough to give an adequate exposure. In most cases the skin may be saved in its entirety, for usually the neoplasm has not extended to it, but in a few cases in which previous treatment has

Fig. 3 Lateral branchial tumor in a patient 48 years of age. duration of tumor growth approximately 18 months. This photograph is included to show our one case in which the location of the lesion was atypical. The incisions which are present were made before the patient was seen here.

caused the tumor to spread to the skin, it must be sacrificed. As is true of dissection of cancer anywhere in the body, the preservation of anatomical structures should not be considered. It is most important that the dissection be made with a sharp knife thus avoiding all traction or pulling of the tissues.

The muscular structures which should be removed are the sternocleidomastoid thyrohyoid and other infrahyoid muscles, the rectus capitis anticus major digastricus and at times the anterior scalenus muscle.

The lymphatics are of little import and should be completely removed. There is little evidence

TABLE II.—DURATION* OF BRANCHIAL LESIONS

	Cysts	Carcinoma

of the occurrence of lymphoedema after the re-

Fig. 4. Branchial tumor on the right side of the neck, duration of tumor growth 3 months. Left, photograph of patient, 50 years of age. Right, section of tumor showing not only malignant change but a few scattered giant cells suggesting an old tuberculous infection.

removal of the lymphatic chains from both sides of the neck. The only vein of any consequence which is involved in the dissection is the deep or internal jugular. This vein has been tied and resected in so many instances that it need only be mentioned.

The important artery to be considered is the common carotid. When this is resected, anastomoses are made through the vertebrals inferior and superior thyroids, and the deep cervical arteries supplying the circle of Willis. The literature shows that the mortality rate following ligation of this blood vessel is 12.5 per cent and that about 25 per cent of the patients show some subsequent mental change. The proportion of deaths and psychoses among older patients after liga-

tion of the common carotid is even higher and since most patients with this disease are beyond middle life, every effort should be made in order to save this vessel.

OPERATIVE RESULTS

The most common immediate operative result is a collection in the wound of a large amount of serum which is troublesome because it tends to push the skin away from what is left of the underlying structures. This can be prevented by the application of large pressure dressings over this area. We use skin clips with a few black silk stays and have found that this is a very satisfactory method of closure.

Of course, as in all elderly patients, the immediate danger is that of pneumonia, and this caused 2 of the 4 postoperative deaths in our series. Of the 2 others, 1 died from shock, and the other following a laryngectomy.

In 1 of the patients in this series a postoperative psychosis developed but there was a history of some senile change before the operation, and at the time of writing this patient is still living 3 months after operation but has shown very little mental improvement.

There usually is no difficulty in the muscular movement of the head after the immediate trauma and stiffness have subsided.

The damage to the sympathetic system is evident immediately and no improvement in this respect is ever noted. The pupil on the side operated upon is contracted and ptosis of the lid develops, caused by a paralysis of Mueller's muscle resulting from the cutting of the superior cervical ganglion. When the vagus nerve is cut,

Fig. 5. Photomicrographs of sections of a branchial tumor removed from a patient 5 years of age, duration of tumor growth 6 weeks. Left, photomicrograph, $\times 100$. Right, photomicrograph showing the definite cystic nature of the lesion, $\times 200$.

Fig. 6. Photomicrographs of sections of a branchial tumor removed from a patient 50 years of age, duration of tumor growth 12 months. Left, photomicrograph, $\times 200$. Right, photomicrograph showing a larger area with a cyst wall in the lower portion, $\times 200$.

an immediate change in the rate of respiration is noted and also a rapid increase in the pulse rate. The vagus nerve on the right side of the neck is supposed to have less influence on the heart and gastro-intestinal tract than does the vagus nerve on the left, although, in our experience, the cutting of this nerve on either side produced little or no permanent effect. Most of the respiratory and cardiac changes disappear within 24 hours.

Paralysis of the vocal cords is permanent, of course, and the patient always has some huskiness of the voice. The phrenic nerve lies beyond the structures involved and is usually avoided at operation, but, if it were cut, there might be a collapse of the lung on that side.

END-RESULTS

In this series of cases, 11 patients were treated by surgery alone. Two died from postoperative bronchopneumonia. Five left the hospital, 4 of them in good condition on discharge, but the fifth was unable to swallow on account of paralysis of the glossopharyngeal nerve. Two of the 4 remaining patients died respectively, 9 and 10 months after operation. Two are still living: 1 in very poor condition at the end of 1 month, and the other is alive at the end of 3 months with a postoperative psychosis.

Six patients were treated by surgery and postoperative deep roentgen radiation. One of these died following a laryngectomy which was performed because of the extension of the tumor into the pyriform sinus. Two others have died, 1 at the end of 3 months after operation after only one course of roentgen radiation; the other at the end of 11 months after operation following three courses of radiation over the entire side of the neck and head. Two are living at the end of 2 months after operation but 1 of these patients is in very poor condition because of metastasis to the lung and the other patient in this group is in very poor condition 4 months after operation.

One patient, who was treated with one course of radiation preceding operation, and postoperative radiation with roentgen rays and 2,080 milligram hours of radium, died 12 months after operation.

Another group of 5 patients was treated only with roentgen radiation distributed over the head and neck. These all received at least 1 complete course averaging about 60 per cent of an erythema dose at each treatment. Two of these patients died within 3 months, and a third lived 7 months. The fourth patient is in poor condition at the end

of 1 month after treatment. The fifth patient is living 4 months after the first treatment and 8 months after the lesion was first noted, and is apparently in good health.

One patient was treated with radium alone, receiving 2,340 milligram hours at the first treatment and 2,600 milligram hours 2 months later and died 6 months after the first treatment.

Four patients were treated with both roentgen and radium radiation and all died within a period of 9 months after the first treatment. The patient who received the smallest dose of X ray and radium lived the shortest length of time after the treatment, and the one who received the largest amount both of X ray and radium had the next shortest survival period, the patient who received the next to the smallest dose lived the longest (9 months).

In 8 cases not included in this series, there was a clinical diagnosis of a branchial tumor but no pathological examination. These patients received no treatment and their average duration of life after their first examination was approximately 6 months.

These data show that the results of treatment of branchial carcinoma are not good, no matter what the treatment, but in view of the fact that Roeder has reported that 1 patient treated by radical operation and roentgen radiation has survived for more than 4½ years, we feel that every patient should be subjected to these therapeutic procedures with the hope that perhaps a few may be definitely benefited.

PATHOLOGY

The pathological picture presented by these cases of branchial carcinoma is that characteristic of squamous cell carcinoma. Grossly, if the origin of the tumor is a cyst, there is usually some evidence of the cyst wall and often a definite capsule infiltrated by the tumor can be demonstrated. The blood supply usually is scanty and gives rise to the frequent areas of necrosis, as well as the hyaline degeneration. Often a flaky yellow semisolid content typical of that seen in a simple cyst is noted, and the neoplastic change may involve only a portion of the cyst lining.

Microscopically there is a fibrous tissue stroma with the tumor cells arranged in whorls of branching cords with no evidence of connective tissue between the cells. In addition, there may be noted nests containing cells more densely packed together, showing typical pearl formation. The cells themselves are polyhedral in shape and irregular in size, with the nuclei taking varying amounts of stain. A frequently noted fact which

TABLE IV —INCIDENCE OF PAIN WITH BRANCHIAL LESIONS

	Cysts		Carcinoma	
	Cases	Per cent	Cases	Per cent
Present	11	8	17	61
Absent	25	96	6	21
Not mentioned	16	96	5	18

is significant of rapid growth is the remarkably large number of mitotic figures, with many of them asymmetrical and bipolar. This growth, together with the poor blood supply leads not only to gross areas of necrosis, but to numerous isolated degenerating cells and cell groups showing karyolysis and isolated groups of nuclear granules (Figs 4, 5 and 6)

PATHOGENESIS

Branchial or branchiogenic carcinomata arise from embryonic rests which for some unknown reason are stimulated into growth. As would be expected therefore, they frequently are associated with branchial cysts, and therefore a study of the embryological etiology of branchial cysts may throw some light upon the pathogenesis of branchial carcinoma.

A brief review of the literature regarding the embryological etiology of branchial cysts shows that there are numerous hypotheses, each and every one of which seems to explain, at least in part, the presence of such abnormalities. The histological elements in these cysts, namely connective, lymphoid, and epithelial tissue, are evident in the embryonic structures in all theories presented. It may be true that each has its individual application and that, when branchial carcinomata are studied, all these hypotheses must at least be considered as factors. The evidence at the present time seems to point toward Wenglowski's theory as the most acceptable.

In 1912 Wenglowski published one of the most important single contributions on the etiology of cervical cysts and fistulae. This has been translated by Meyer. His papers are the result of intensive work over a period of 5 years. He concluded that sufficient evidence is shown to prove that branchiogenic rests may be limited above by the jaw and below by the hyoid bone—that cysts and sinuses found outside this area along the mesial border of the sternocleidomastoid muscle and above the suprasternal notch are anomalies occurring in the so called "thymacopharyngeal duct."

Christopher greeted this theory very favorably and felt that it completely abolished the branchiogenic theory regarding the origin of branchial carcinoma. Shedden was hesitant and presented a table of Wenglowski's conclusions as criticized by Kingsley which substantiated his doubts concerning the ability of this hypothesis to explain all the abnormalities in this area.

Frazer (5) suggested that these abnormalities may be the result of "placodal cysts or ducts, or of the ectodermal external pharyngeal ducts which are connected with the entodermal pouches, and this author has also shown the embryological relationship between the branchial cysts and the hypoglossal nerve. Hyndman and Light suggested essentially the same idea.

Not to be forgotten are the important early contributions to this subject by Rathke, Bland-Sutton and Cusack. The last 2 authors concluded that if any abnormality in growth should cause the arches to obliterate the grooves, a fistula or cyst might result and that these pathological conditions might occur at levels corresponding to the various unobliterated clefts. Another interesting hypothesis was advanced by Rahl who felt that these anomalies arise from an improper obliteration of the cervical sinuses.

SUMMARY

1. Branchial carcinoma is a distinct pathological entity. It is comparatively rare less than 100 cases have been reported in the literature.

2. Branchial carcinomata arise from embryonic rests which for some unknown reason are stimulated into growth.

3. Because of the rarity of this lesion and its high degree of malignancy which demands every resource for palliation and prolongation of life, a series of 28 cases, diagnosed pathologically as branchial carcinoma, is reviewed with special reference to treatment.

4. The clinical picture is described and the conditions to be considered in the differential diagnosis are listed.

5. The method of treatment by surgery and by radiation is described, and the immediate and remote results are recorded.

6. Only palliative results and the prolongation of life can be expected from any treatment, as the disease is usually rapidly fatal. From available evidence it seems probable that radical excision followed by radiation offers the best chance of relief to the patient with branchiogenic carcinoma.

The authors wish to thank Miss Amy Rowland and Dr. Allen Graham for their assistance in producing this paper.

RUPTURE OF THE KIDNEY PELVIS

REVIEW OF THE LITERATURE¹

BENJAMIN S ABESHOUSE, M D BALTIMORE, MARYLAND

From the Urological Clinic, Sinai Hospital

RUPTURE of the kidney pelvis is a relatively rare lesion of the kidney. The author has collected 61 cases of rupture of the kidney pelvis from the literature and has added 3 personal cases. In this series of 64 cases, there are 31 cases of traumatic rupture, 26 of the spontaneous type, 3 following instrumentation of the ureter and 4 following pyelography. These cases are grouped under their respective headings in the bibliography. It is possible and indeed very probable, that many more similar cases have been encountered but have not been reported or are reported in connection with some other renal lesion, i.e. ruptured hydronephrosis, renocolic fistula, etc. and hence are not readily discernible in the rapidly increasing urological literature.

In this series, the author has collected only those cases in which the rupture is strictly confined to the pelvis of the kidney and has excluded those cases (a) in which the rupture has occurred at a terminal calyx (Fritz, 2 cases; Henline) (b) in which an associated rupture or tear occurred in the renal parenchyma and (c) in which a perirenal, psoas or vertebral abscess opened into the renal pelvis.

True rupture of the kidney pelvis may be conveniently classified into the following two types: traumatic and non-traumatic or spontaneous. The traumatic type of ruptured pelvis, unassociated with a parenchymal injury is more frequently encountered than the spontaneous type and is usually observed in those cases of ruptured hydronephrosis in which the external force is sufficient to produce an uncomplicated rupture of the thin pelvic walls found in pyelectasis. The spontaneous type of ruptured pelvis usually occurs in those patients who have associated pathology in the upper urinary tract, i.e. pyelitis or hydronephrosis secondary to an inflammatory lesion or congenital or acquired obstruction (stone stricture, etc.) of the ureter or pelvis.

ETIOLOGY

There are various extrinsic and intrinsic factors or conditions which may serve as predisposing or etiological agents in the production of a rupture or perforation of the renal pelvis. The most common extrinsic factor is trauma of a direct or indirect nature. The most important intrinsic

factors are (1) infections of the renal pelvis, (2) stone or stricture in the pelvis or ureter, (3) hydronephrosis, (4) operative defects, (5) instrumentation, i.e. ureteral catheterization and (6) syringe pressure pyelography. While some of these conditions bear a greater etiological significance than others, a brief consideration of each is presented.

Trauma. The etiological relationship of trauma to rupture of the kidney parenchyma has been repeatedly emphasized by many writers. A review of the important contributions to this subject is in order since the external forces concerned in the production of a rupture of the kidney pelvis are essentially the same as those responsible for a rupture of the kidney parenchyma. Rayer and Tuffier were the first to emphasize the fact that an injury to the kidney may be caused by the jarring from a direct blow on the body. LeDentu explained kidney injuries on the same basis as a brain injury due to a blow on the opposite side (*contre coup*). Schede pointed out the possibility of throwing a distended kidney against the transverse process of a vertebra while Morris attributed a similar rôle to the floating ribs. Kruster has stressed the effect of hydraulic pressure acting through full blood vessels and a distended pelvis and causing the organ to burst along lines which radiate for the most part from the pelvis and tubules toward the point of maximum impact of the lower ribs, the opposing resistance being supplied by the vertebral column. Guterbock has suggested the possibility of a force so exerted that the poles of the kidneys are squeezed together producing transverse fissures and conceivable ruptures. Keen maintained that the line of cleavage follows the direction of the uriniferous tubules. Grawitz explained the tendency to radial fissuring on the basis of the fetal arrangements of the kidney but this theory lacks histological proof.

The most frequent modes of injury to the kidney parenchyma or pelvis are (1) the application of direct force against the kidney, i.e., a fall, blow or compression which drives the kidney against the lower ribs or against the transverse processes or bodies of the lumbar vertebra, (2) the application of indirect force producing a concussion such as may occur following (a) jarring the body as in landing on the feet after a fall, (b) undue muscular

effort as in sneezing, coughing, straining, lifting heavy objects, etc., (c) acute flexion or other sudden movements of the body, (3) penetrating forces such as a gunshot injury, stabbing, etc. The latter type is more likely to result in an injury to the parenchyma or vascular pedicle than to the pelvis.

At times it appears to be well nigh impossible to explain the occurrence of a rupture of the kidney parenchyma or pelvis following what appears to be a slight injury or inadequate force. The extent of the damage to the renal parenchyma or pelvis may be out of proportion to the degree or amount of the force. The direction of the force and the pathological and physiological condition of the kidney parenchyma and pelvis often determine the type of injury to these structures. It is the general impression that an infection or distention of the kidney parenchyma or pelvis greatly increases the susceptibility of that organ to rupture by external violence. This is borne out by the increasing number of reports of rupture of hydronephrotic kidneys in the recent literature. In many cases of traumatic rupture of the kidney, the laceration or tear in the kidney parenchyma is very often accompanied by a coincidental tear in the renal pelvis or the parenchymal rupture extends directly into the pelvis but in such cases the pelvic rupture is always overshadowed by and secondary in importance to the parenchymal injury.

Infection The etiological significance of an acute or chronic infection of the pelvic walls in production of a traumatic or spontaneous rupture of the pelvis has not been clearly established. The presence of such an infection, unaccompanied by a pelvic or ureteral obstruction, apparently has but little causative significance in cases of ruptured pelvis due to external violence other than producing a potential weakness of the pelvic walls which increases the susceptibility of the tissues to any type of injury. Undoubtedly a pelvic infection plays a more important rôle in etiology of the spontaneous type of rupture. This contention is based on the fact that a rupture of the pelvis is more likely to occur in those cases where the pelvic walls have been weakened by an acute or chronic inflammatory process and are subjected to the influence of other factors such as an increased intrapelvic pressure or irritation from an impacted irregular stone. It can be readily understood how an ulcer with a thin base and inflamed margins may serve as a potential site for a perforation or rupture under similar conditions. Two cases of ruptured pelvis secondary to a chronic pyelonephritis were reported by Fritz and Mathe. In

10 cases the rupture occurred in a pyonephrotic kidney secondary to a calculus or stricture in the ureter or pelvis.

Stone or stricture in the upper urinary tract The presence of a stone in the ureter or pelvis may influence, directly or indirectly, the development of a traumatic or spontaneous rupture of the pelvis. The pathological sequelae of stone in the upper urinary tract, i.e. obstruction, retention, infection, and ulceration are well recognized. Thus a ureteral or pelvic stone may be indirectly responsible for the rupture of the pelvis by virtue of the fact that these accompanying secondary changes in the pelvic walls increase the susceptibility of this structure to rupture following a mild or severe traumatic insult. If an infection supervenes, the thinned pelvic walls resulting from pyelectasis are further weakened so that any extrinsic or intrinsic pressure may produce a rupture of the pelvis. In the analysis of the reported cases it was found that a stone was present at the ureteropelvic junction in 3 cases, in the ureter in 9 cases, in the pelvis or calyces in 14 cases.

A stone in the upper urinary tract may be the direct cause of a pelvic rupture. When the calculus is small, smooth and movable, the irritation and ulceration of the mucous membrane is insignificant. If the stone is large with irregular jagged surfaces and in a more or less fixed position, the ulcerating process may be more extensive and produce a localized area of necrosis which serves as an admirable site for spontaneous perforation. Should the stone be encysted or impacted, the ulceration progresses rapidly and deeply involving all the layers of the pelvic wall, and soon results in a perforation with the escape of the pelvic contents i.e., infected urine and occasionally the stone, into the peripelvic and perirenal tissues.

Any intrinsic or extrinsic obstruction of the ureter may be indirectly responsible for a rupture of the pelvis by virtue of subsequent development of a hydronephrosis or pyonephrosis. In the case reported by Schmidt, the pelvic rupture occurred in a hydronephrotic kidney secondary to an aberrant vessel crossing the ureteropelvic junction. In one of the author's cases, a stricture at the ureteropelvic junction was the probable etiological factor responsible for the pelvic rupture.

Hydronephrosis In 1909 Legueu distinguished three types of hydronephrosis associated with trauma, viz (1) true traumatic hydronephrosis—this type has all the physical characteristics of an ordinary hydronephrosis but owes its origin to some traumatism. The dilatation of the kidney pelvis occurs at the expense of the kidney paren-

chyma and is the result of a more or less complete obstruction of the ureter or pelvis by either a blood clot or a faulty reparative process in the injured kidney pelvis or ureter (2) pseudotraumatic hydronephrosis—this type is the result of an injury to the kidney pelvis or ureter which is followed by an extravasation of urine and occasionally blood, into the surrounding tissues, and by the development of a well defined sac about the extravasate. This condition is sometimes called pseudohydronephrosis and is seen most frequently in young individuals and (3) ruptured hydronephrosis—in this type a rupture of a pre-existing congenital or acquired hydronephrotic kidney occurs as the result of direct or indirect trauma.

It is the latter type (group 3) which is of particular interest from the standpoint of rupture of the kidney pelvis, for by far the greatest percentage of cases of ruptured pelvis are cases of ruptured hydronephrosis. The author has reviewed 72 cases of ruptured hydronephrosis of both the traumatic and spontaneous forms and found that in 17 cases the rupture or tear was in the mucous membrane of the pelvis. An analysis of this series of 72 cases reveals the fact that ruptured hydronephrosis is most frequently associated with direct trauma although indirect trauma and muscular action is the responsible factor in a few cases.

A very slight injury may be the cause of rupture of a hydronephrotic kidney especially in children and adolescents as occurred in Lazarus a patient who developed a tear in the renal pelvis following a glancing blow received during a basketball game. In Schmidt's case, the rupture occurred while the patient was rowing. Herman states that in about 50 per cent of the cases of ruptured hydronephrosis, the renal injury followed what appeared to be insignificant trauma or was of such mild intensity and degree that it is safe to assume that similar injury would not cause more than a superficial bruise in a normal individual.

It is interesting to note that several cases of spontaneous rupture of a hydronephrosis have been reported. In many of these so called spontaneous ruptures, it is possible and very probable that either or both the patient and the physician have overlooked some mild form of trauma. However there are several cases of spontaneous ruptured hydronephrosis in which a traumatic factor can be eliminated but careful examination in these cases practically always reveals some secondary etiological factor i.e. pyelitis or stone.

While it is true that mild trauma or muscular action may produce a ruptured hydronephrosis in children it is difficult to conceive how these same agents can produce the same effects in adults with hydronephrosis. It has been the experience of every urologist to frequently encounter men with very large hydronephroses who are employed at very arduous mechanical trades or at heavy manual labor requiring unusual muscular effort and considerable use of intra-abdominal pressure and who continue to work at their trades for many years without damage to their diseased kidneys. A possible explanation for the greater incidence of ruptured hydronephrosis and incidentally ruptured pelvis in children and young adults is the fact that the kidney is situated at a lower level in children as a result of the persistence of the infantile type of psoas as pointed out by Aglave. Other predisposing factors in children are the lack of protection of the lower ribs as suggested by Gibson and the diminished amount of perinephritic fat and increased tension of the posterior parietal peritoneum in the region of the kidney as maintained by Harrigan. The abdominal musculature is better developed in adults and can help ward off or minimize the effects of traumatic forces directed against the kidney.

Rupture of the pelvis following plastic operation. Spontaneous rupture or perforation may occur several weeks or months after a plastic operation on the renal pelvis. The occurrence of a rupture or perforation following a plastic operation on the pelvis may be attributed to a faulty operation and is due to either a recurrence of the old obstruction or to the production of a new obstruction. In either instance there results an increased back pressure which is exerted on the potentially weakened portion of the pelvis namely the suture line. These untoward results were frequently encountered in the early days of conservative plastic operations on the renal pelvis and were responsible for the slow recognition accorded this deserving operative procedure. However when the proper precautions are taken at the time of operation to insure and institute good drainage by inserting a nephrostomy tube splitting the ureter etc., accurate healing occurs and unpleasant accidents are avoided.

Walters recently emphasized the postoperative complications which are likely to occur following plastic operations on the renal pelvis for hydronephrosis. He stressed (1) the leakage of urine at the point of anastomosis with perineal extravasation (2) retention of the urine in the kidney leading to pyelonephritis or cortical

abscesses and (3) ureteral obstruction at or below the pelvic incision with a persisting urinary fistula from the site of pelvic anastomosis. Three of the 8 cases, in which resection of the pelvis was done, later required a secondary nephrectomy due to persistent urinary fistula as a result of occlusion of the ureter by postoperative infection around the ureter (1 case) and pyelonephritis and cortical abscesses (2 cases).

Rupture of the pelvis following instrumentation of the ureter. Perforation of the renal pelvis by a ureteral catheter has been known to occur in rare instances. Hunner reviewed a series of over 20,000 cystoscopic treatments of the ureter by the Kelly method and reported 21 accidents which included 12 personal cases and 9 cases occurring in the practice of his associates. An incidence of one accident in each thousand ureteral catheterizations indicates a very low morbidity. Nevertheless it serves to emphasize the fact that this procedure may be attended by an unpleasant complication in hands of inexperienced cystoscopists. In this series of 21 cases there were 4 cases in which the perforation occurred in the pelvis or in the upper third of the ureter near the ureteropelvic junction.

Wesson states that the wall of a normal ureter cannot be punctured by the ordinary ureteral catheter and maintains that it is doubtful if a diseased ureter can be perforated unless a deep ulcer is present. He pointed out that when the ordinary catheter is passed through the cystoscope and the tip of the catheter meets with the resistance of the urethral wall, the catheter will buckle. Similar results were obtained when a maximum pressure was exerted in passing a catheter up the ureter through the bladder of freshly obtained autopsy specimens. He is of the opinion that perforation can occur if a wire stylet is used or the catheter is equipped with a whalebone tip such as is used in the Kelly method of direct cystoscopy. In this connection, it is well to point out the danger of perforating the ureter when any one of the various metallic ureteral stone extractors is used. Wesson also showed that it is impossible to perforate the kidney capsule with an ordinary ureteral catheter.

Rupture of the pelvis as a complication of syringe pressure pyelography. One cannot stress too strongly the danger of producing a rupture of the pelvis in employing the syringe method of pyelography. Any pelvis or ureter whose walls have been weakened by the presence of a stone, chronic infection, abscess formation, tumor, etc., is a potential site for a rupture when too much pressure is exerted in injecting the pyelographic

medium as has been pointed out by Hoffman, Hunner, Mathe, Hartman, Wesson and Kindall. The syringe method of injecting the pyelographic fluid without manometric control should not be used in the diagnosis of those cases in which an impacted ureteral or pelvic calculus, chronic infection, abscess formation or tumor of the pelvis is suspected. The low pressure gravity is a safer procedure and practically devoid of the danger of perforation. In his discussion of Kindall's paper, Hunner stated that spontaneous rupture may follow even the gravity method if stricture or some other form of obstruction causes prolonged trapping of the fluid. Hoffman has reported 3 cases of perirenal suppuration following the use of 5 per cent collargol as a pyelographic medium. He maintained that under increased pressure, the collargol passes into the canaliculi and thence by rupture or diffusion reaches the perirenal tissues causing necrosis. In 1 case, the rupture occurred in the pelvis of a hydronephrotic kidney and spread into the peritoneal cavity. Kindall has recently reported 2 interesting cases of rupture following syringe pressure pyelograms. In 1 patient a calculus was present in the lower calyx of the kidney and a rupture of the kidney occurred and 2 days later a rupture of the ureter. The other patient had calculi in the kidney pelvis and ureter and developed a rupture of the pelvis.

PATHOLOGY

The pelvic lesion encountered at operation or autopsy may be either a laceration or a perforation on one of the surfaces of the pelvis, usually the posterior surface. Occasionally two tears may be present in the same pelvis. The laceration or tear in the pelvis is usually radial in character especially in cases of a ruptured hydronephrotic pelvis and appears to extend from a point near the ureteropelvic junction toward the hilum of the kidney in a direction corresponding to that of the uriniferous tubules. The size of a tear is more or less in proportion to the degree of back pressure and increased intrapelvic pressure causing the rupture. The nature and the direction of the pelvic laceration in these cases tends to indicate that the lesion is the result of a bursting rather than a break or crushing. This conforms with Kuster's theory on the mode of kidney rupture.

A pathologically or physiologically distended kidney pelvis ruptures more easily and following a lesser degree of violence than a normal undistended kidney. Furthermore, the extrarenal type of pelvis is more susceptible to rupture than the intrarenal type. In cases of rupture of a normal

kidney due to external violence, the parenchyma, being the softest and weakest portion of the kidney usually gives way first causing a tear which may extend into the capsule. However if the pelvic wall has been weakened by a chronic infection or hydronephrosis, the rupture may be strictly limited to the pelvis. Occasionally it may involve both the pelvis and the parenchyma. Spontaneous rupture of the kidney pelvis occurs only in those cases in which the pelvis has been pathologically weakened by dilatation or infection. The most common type of spontaneous rupture is rupture of the pelvis of a hydronephrosis secondary to an obstruction of the ureter or pelvis by a calculus. The rupture occurs as a result of a sudden or gradual alteration in the increased back pressure caused by an obstructive lesion in the upper urinary tract. Occasionally a spontaneous rupture of the pelvis is caused by perforation of an impacted calculus. There have been no cases reported of spontaneous rupture secondary to a neoplasm of the renal pelvis.

Several cases have been reported in which the pelvis or ureter at the ureteropelvic junction have been partially or completely severed as a result of violence or external force directed against the distended kidney. It may be impossible to differentiate the rupture of the pelvis from a similar lesion of the upper portion of the ureter from a clinical standpoint. However from an anatomical standpoint, a tear or perforation at the ureteropelvic junction may be considered just as much a lesion of the pelvis as of the ureter. In fact, it is often impossible to determine on close inspection of the affected organ, either at operation or at autopsy, the exact location or limitation of the rupture. A careful survey of the literature reveals the fact that true intraparietal rupture of the ureter is an exceedingly rare condition.

The most striking pathological feature of ruptured pelvis is the extravasation of urine into the surrounding tissues. This condition is rarely accompanied by the extravasation of blood inasmuch as there are no end arteries in the pelvis. The presence of blood in the extravasate is indicative of rupture of the parenchyma or a laceration of one or more of the blood vessels in the hilum of the kidney. It is possible that at the time of rupture of the pelvis there may develop an intrarenal rupture in the region of the pyramids of varying degree which may be responsible for a slight amount of bleeding and the presence of a small amount of blood in the extravasate.

When the actual amount of urine escaping through the pelvic rupture or perforation is scant and the urine sterile the tissue reaction is prompt

and localization of the extravasate may ensue with or without the subsequent formation of a circumscribed abscess in the peripelvic or perirenal tissues. If the extravasated urine is walled off and absorbed, these patients may recover without any surgical intervention and it is conceivable that cases of this type occur but are not recognized.

When the extravasation of urine is more extensive or continues for some period of time after the rupture, the tissue reaction may be less efficient particularly if the urine contains pathogenic organisms. In such a case the extravasated urine causes a diffuse inflammation in the surrounding tissues which soon results in suppuration and a rapidly progressive perirenal abscess. Occasionally the perirenal abscess may rupture into the lung (Mathe) large bowel (Wesson) peritoneal cavity (Hammel, Roet, Kapel) or externally into the skin of the loin giving rise to the formation of a temporary or permanent fistula (Mathe, Turner Higgins, and Hicken, and one of the authors' cases).

Vermooten and McKeown recently reviewed 34 cases of renal colic fistula. In 2 instances (Watson and Cunningham, Fuller) the fistula was found between the renal pelvis and the bowel. In all the other cases, the fistulous tract started in a calyx passing through the kidney substance into the bowel. They pointed out that renocolic fistulae are always secondary to long standing suppurative lesions of the kidney which, as a rule, are associated with either a chronic pyelonephritis or a perinephritic abscess.

The author has reviewed the cases of fistula formation between the renal pelvis and the large and small bowel or bronchus reported in the literature and has recorded them under their respective headings in the bibliography. These cases are not included in the final tabulation of true cases of ruptured pelvis due to the fact that the etiological relationship is by no means clearly established in these cases.

The immediate pathological changes occurring in the affected kidney following a pelvic rupture depends upon the condition of the kidney before the injury and the extent of the inflammatory process in the perirenal tissues following the injury. The subsequent perirenal infection may assume the characteristics of an extensive gangrenous process or a devastating phlegmon which soon involves the entire perirenal tissues. The infection may invade the kidney proper and produce many cortical abscesses or a diffuse pyelonephritis.

The permanent pathological sequelae which may follow the rupture of the pelvis depend

upon whether or not treatment is instituted. In those patients who recover without operative intervention due to the fact that the extravasation is slight and localization with absorption takes place there may develop a cicatrizing or sclerotic process in the perinephritic tissues which may or may not cause trouble in the future. Occasionally the reparative process in the region of the tear is faulty and there develops a stenosis which may be responsible for the further development of a hydronephrosis or even stone formation. If treatment consists solely of preliminary incision and drainage and no attention is paid to the underlying lesion the after effects of the rupture resulting from the suppurative process in the perirenal tissues may be manifested in the form of a permanent fistula kidney atrophy infection of the opposite kidney parenchymatous or interstitial nephritis, or future stone formation. In those cases in which the rupture of the pelvis occurs in the form of a partial or complete severance or tearing of the pelvis at the ureteropelvic junction or in which the pelvis is completely severed from its attachments at the hilum of the kidney primary healing is not likely to occur and there results a permanent fistula. In an occasional case, the injured tissues may heal with cicatricial contraction at the site of rupture which results in a partial or intermittent form of hydronephrosis as occurred in the case which has been reported by Bailey.

While this paper is particularly concerned with rupture of the kidney pelvis proper it is interesting to note that rupture of the pelvis may also occur in any of its major or minor calyces. When the calyceal rupture is due to trauma, the laceration may extend partially or completely through the adjacent parenchyma (subparietal rupture) which results in an extravasation of blood and urine below the true capsule of the kidney and heals with little or no permanent damage to the kidney. Occasionally the calyceal rupture results in a distention of the calyx due to an intrarenal extravasation of urine which may extend through the cortex and under the kidney capsule. This process soon becomes walled off producing a cystic dilatation whose lining appears to be a continuation of the pelvic and calyceal mucous membrane. This walled off sac is known as a pseudohydronephrosis which may later rupture as in the case reported by Babitzki. In the same manner a pseudohydronephrosis may develop following a rupture of the true pelvis. This condition occurred in 6 cases of traumatic rupture (Hawkins, Stanley, Dodge, Wildbolz, and Bretnanno 2 cases).

AGE AND SEX INCIDENCE

The age and sex of the patients bear no unusual significance in cases of ruptured pelvis. The age and sex act as predetermining factors only in so far as they predispose to the development of an upper urinary tract lesion which increases the susceptibility of the kidney pelvis to ruptures. i.e. the development of a congenital hydronephrosis in infants and children the occurrence of pyelitis of pregnancy hydronephrosis ptosis and stone formation in women in the childbearing period. There were 4 cases of traumatic rupture in the first decade (Hawkins, 6 years, McAlpine, 7 years, Weason, 8 years and Martin 8 years) and 4 cases in the second decade (Croft, 12 years, Lazarus, 15 years, Ewell 16 years and Rowland 18 years). The youngest patient in the series of cases reviewed was 6 years of age (Hawkins) the oldest 77 years (author's case). The average age was 35.6 years. There were twice as many males (39 cases) as females (19 cases). This latter observation may be explained by the fact that the greatest number of cases were of the traumatic type and in this age of automobiles, trains and machinery and of competitive sports, men are subjected to greater hazards than women. The left kidney was the site of the pelvic rupture in 35 cases and the right kidney in 22 cases. There was 1 case of bilateral rupture (avulsion) reported by Osgood and Campbell.

SYMPTOMATOLOGY

There is no definite symptom complex associated with rupture of the kidney pelvis inasmuch as the presenting symptoms may differ in the traumatic and spontaneous types of pelvic rupture. The clinical signs and symptoms associated with this condition vary and are more or less dependent upon the etiological factor producing the lesion the associated pathological process present in the affected kidney and the length of time elapsing until the patient first comes under observation. In general it might be stated that the most prominent signs and symptoms of ruptured pelvis are those attributable to perirenal extravasation of urine and perirenal abscess formation. The symptoms of ruptured pelvis may be conveniently classed into the following two groups: general and localized.

General. From a clinical standpoint, ruptures of the pelvis may be divided into an acute and chronic form. The acute group includes those cases of sudden rupture of the pelvis secondary to trauma. In the acute form the patient appears to be acutely ill soon after the rupture has occurred as a result of the sudden escape of urine producing

Fig. 3. Case 2. Pyelogram taken in 1933. The pelvis and ureter of the upper rudimentary segment of the left double kidney has been filled with sodium iodide (13.5 per cent). The large branched calculus occupying the pelvis of the lower segment of the left kidney is clearly shown. The round shadow in the region of the upper pole of the right kidney is a calculus. A pyelogram of the right kidney which was taken several weeks later showed a moderate dilatation of the pelvis and the calculus in the terminal portion of the upper major calyx. Further pyelographic studies of the left double kidney showed a large pyonephrosis of the lower segment but the roentgenograms were too faint for photographic reproduction.

resumed as soon as the initial shock wears off. In cases of ruptured pelvis, the fact that urine is not obtained from the injured kidney may be incorrectly attributed to anuria, whereas the kidney may still retain its secretory function and urine, instead of passing down the ureter, extravasates in the perirenal tissues, and occasionally in the peritoneal cavity or bowel (Wesson, Mathe). A true unilateral anuria on the affected side may develop as a result of the pressure effect of the perirenal extravasation upon the renal pedicle.

Such urinary symptoms as urgency, frequency, dysuria, and tenesmus are uncommon. The occurrence of these symptoms would tend to indicate the presence of an associated obstructive lesion at the bladder neck or a secondary inflammatory lesion in the bladder. Hematuria is conspicuous

by its absence in cases in which the rupture is strictly confined to the pelvis in contradistinction to rupture of the parenchyma in which instance it is a very important diagnostic sign. If the rupture of pelvis is due to trauma and there is a minute intrarenal parenchymal tear or a rupture of a small intrarenal blood vessel in or near the pelvis, i.e. small blood vessel in the pyramids, hematuria may occur at the time of a rupture but soon clears up. The urinary findings are most commonly those associated with an acute progressive toxemia, i.e. a trace of albumin, an occasional red or white blood cell and casts.

DIAGNOSIS

The diagnosis of ruptured pelvis is always difficult. A review of the literature reveals the fact that the majority of the reported cases remained undiagnosed until the time of operation or at autopsy due to the rarity of the condition and the uncertainty of the clinical signs and symptoms. In those few cases in which a correct pre-operative diagnosis was made, it was necessary to resort to other diagnostic measures, i.e. cystoscopy and pyelography to establish the diagnosis.

A careful history in every case may be of inestimable assistance in directing the examiner to the possible existence of such a lesion. An antecedent history of renal colic due to stone in the ureter or pelvis is of definite significance, particularly in cases of rupture secondary to calculus obstruction of the ureter. The knowledge of the presence of an inflammatory or obstructive lesion in the upper ureter or pelvis secondary to a stone or stricture in the upper urinary tract in a patient who complains of a sudden severe pain in the renal region and presents a palpable tender mass with muscular rigidity and spasticity over the affected area, accompanied by chills, fever, nausea and vomiting and rapidly followed by signs of collapse or a severe toxemia, should cause the examiner to suspect a rupture of the pelvis, though actually the diagnosis must be confirmed by pyelographic study or operation. It may even be impossible to establish the diagnosis when cystoscopy and pyelography are undertaken inasmuch as the offending calculus may totally occlude the ureter or ureteropelvic junction rendering it impossible to pass a ureteral catheter or inject a pyelographic medium beyond the obstruction.

Cystoscopy with bilateral ureteral catheterization has proved to be one of the most valuable diagnostic procedures available. Cystoscopic examination is often undertaken in the hope of relieving an acute renal infection or a ureteral

block with acute retention of urine in the pelvis and the true nature of the upper urinary tract lesion is then disclosed. When the catheter fails to reach the kidney pelvis due to an obstructing ureteral calculus, the urologist may be misled into believing that the calculus is the sole lesion producing the symptoms and may overlook the more serious lesion in the kidney pelvis. Thus, the correct diagnosis of pelvic rupture with perirenal extravasation is undetermined or discovered later at operation or autopsy. If the catheter can be passed into the kidney pelvis or zone of extravasation clear urine or actual pus may be obtained which should make the urologist suspicious of a pelvic rupture. The rate and amount of urine flowing from the catheter on the affected side should be carefully observed. A large amount of urine aspirated from the perirenal space through the pelvic tear is a presumptive diagnostic sign of ruptured pelvis. In some cases the urologist is tempted to and does leave the catheter in the pelvis for several days in the hope that drainage of the infected area will result in a subsidence of fever and sepsis and postpones pyelography and operation until a later date with serious consequences.

Differential renal functional tests (phenolsulphonphthalein, indigo carmine, methylene blue etc.) are of little value in establishing the diagnosis of ruptured pelvis or in determining the function of the injured kidney. The same may be said of the value of blood urea, non protein nitrogen etc. As a result of a pelvic tear or perforation, the urine escapes into the perirenal tissues and very little passes down the ureter with a consequent inaccurate determination of renal function. The result of these tests may show a complete loss of function in the affected kidney which may only be temporary if the rupture occurs in a congenitally normal kidney and permanent if the rupture occurs in a diseased kidney.

There appears to be a divergence of opinion as to the wisdom of employing pyelography in the diagnosis of injuries to the kidney parenchyma and pelvis. Luckett and Friedman strongly urged its use in the diagnosis of kidney injuries. They pointed out that the location and extent of kidney injury could be determined by the dissemination of the pyelographic medium within the kidney substance or outside the confines of the kidney pelvis or capsule. They also emphasized the fact that from the pyelographic findings it is possible to determine whether surgical interference is necessary without waiting for secondary symptoms or complications as an indication for such

Fig 4. Case 3. Photograph of the left double kidney removed at autopsy. The arrow points to the perforation in the posterior aspect of pelvis of the lower segment. The large branched calculus occluding the intrarenal portion of the lower pelvis can be seen. The lower kidney segment shows the typical changes of a large multilocular pyonephrosis. The upper rudimentary segment is seen beneath the scale and shows relatively little change in the parenchyma. The small pelvis in the upper segment and a portion of partially duplicated ureters may also be seen.

interference. Beach maintained that pyelography is a harmless procedure and should be employed immediately in every case of suspected kidney injury. Herman and Wallenstein emphasized its value in the diagnosis of ruptured hydronephrosis and Geisinger stressed its importance in the diagnosis of extravasation from the ureter.

It is quite obvious that pyelography should never be attempted in those patients who are critically ill or in shock. In the past, the objection to pyelography was based on the supposed danger attending the injection of an irritating pyelographic medium i.e., sodium iodide, into an injured kidney or into the perirenal tissues. Fritz and Geisinger maintain that the distribution of a small amount of sodium mercuric iodide into the tissues already infiltrated with pus and urine is not likely to be productive of any serious sequelae particularly if very low pressure (gravity method) is used in injecting the pyelographic medium. The danger of injecting an irritating electrolyte (sodium iodide) into the perirenal tissues can be readily obviated by employing 15 per cent skiodan which is non-toxic, non-irritating and non-haemolytic. Hartman and Kindall have pointed out that the usual criteria i.e., pain and volume of pyelographic medium injected are usually insufficient to judge over distention in a traumatized kidney where the

dition demanding prompt and efficient treatment. Immediate incision and drainage of the perirenal tissues is imperative and, in fact, may even be life saving in effect. After preliminary drainage has been established the true nature of the condition or the underlying cause can be determined later or not as circumstances dictate.

Death may occur as a result of this severe infection, toxemia, or septicemia. If the patient survives the initial stage complications may ensue, viz. the perforation of the perirenal abscess into the peritoneum, abdominal viscera or through the diaphragm, and the patient succumbs after a protracted period of wasting and suffering. The presence of an associated intra-abdominal lesion or a peritoneal tear occurring at the time of the pelvic injury offers a most unfavorable prognosis. The presence of a disease process in the opposite uninjured kidney may seriously endanger the patient's life inasmuch as the injured kidney in most instances is damaged beyond repair and the entire secretory burden is thrust upon an impaired organ. As far as we have been able to ascertain, there are no cases reported in which a simultaneous bilateral rupture of the kidney pelvis occurred with the exception of Campbell's two cases: chemical necrosis following the intrapelvic injection of sodium hydroxide and bilateral avulsion of pelvis following a fall. Such an accident would almost certainly lead to an early demise.

According to Morris, the prognosis in cases of rupture of the renal parenchyma, renal pelvis or ureter is less favorable than in rupture of any abdominal viscera. This pessimistic attitude may be attributed to the fact that the high mortality figures associated with rupture of any portion of the kidney in the past were based on the reports of isolated cases or series of grave cases. However, the recent refinements in urological and roentgenological diagnosis and the improvement in surgical technique have been responsible for a marked reduction of the mortality and morbidity of this condition. In the series of cases collected by the author the immediate operative mortality was 6 per cent (3 deaths in 50 operative cases) which is a very modest figure when one considers that they include cases in which preliminary drainage was delayed intentionally or non-intentionally by the patient or the surgeon.

CASE REPORTS

CASE 1: N. M., a man 77 years of age, an inmate of the Aged Home, was admitted to the hospital on May 6, 1913, with the complaint of pain in his left kidney region. He had had a bilateral ligation of the vas deferens and a perineal prostatectomy 1 year previously with an excellent functional result. Four weeks before admission to the

hospital the patient developed a sudden sharp pain in his left lumbar region radiating to the groin. The pain persisted for several hours and was accompanied by nausea, vomiting and fever. A dull pain persisted in the left lumbar region and left upper quadrant after the first attack. The patient gave a history of nocturia (1 to 3 times) burning, hesitancy and urgency but no history of passing a calculus or hematuria or trauma.

Physical examination was negative except for definite fulness in the left upper quadrant extending from the left flank to the mid-epigastrium. A mass about the size of a large orange was felt and appeared to be smooth and tender to touch. There was no ballottement or fluctuation. There was tenderness in the left costovertebral angle. The leucocyte count was 10,000 with 86 per cent polymorphonuclears. The urine showed 30 to 30 pus cells per high power field.

Following admission to the hospital the temperature remained slightly elevated for 4 days. Cystoscopy and pyelography were then performed. Two small calculi in the bladder were seen and removed by a rongeur. Pyelogram of the left kidney showed extravasation of dye around the pelvis of the kidney. The pelvis and calyces appeared to be dilated. A tentative diagnosis of left pyonephrosis with a peripelvic abscess due to rupture of the pelvis was made. He was kept under observation for several days but as he continued to show a slight daily elevation in temperature and the mass appeared to be increasing in size and became more tender on palpation, operative intervention was decided upon. Fourteen days after his admission to the hospital a subcapsular nephrectomy was performed under spinal anesthesia. The abscess contained approximately 3 ounces of a thick, green, foul-smelling pus which was found on the posterior aspect of the lower pole of the kidney and extended around anteriorly to the region of the pelvis. Two perforations were noted in the region of the ureteropelvic junction. Culture of the pus from the abscess revealed *Bacillus pyocyaneus*. The patient had a stormy convalescence for the first few weeks after operation. The wound broke down and the patient developed furuncles in the left lumbar region culminating in a fairly large carbuncle, which responded slowly to treatment. He was discharged from the hospital 34 days after operation in good condition with the wound entirely healed except for a small sinus tract which healed 3 weeks later.

Pathological examination showed the usual changes of arteriosclerosis and pyonephrosis. The ureter was constricted at the ureteropelvic junction. Above this point of constriction, there was a small perforation 3 millimeters in diameter and a millimeter in diameter respectively.

It is difficult to determine the etiological factor responsible for the perforations of the pelvis and ureter in this case. It is the author's opinion that the essential pathological changes present in the affected kidney i. e. pyonephrosis, pyelonephritis, and stricture of the ureteropelvic junction, were secondary to the benign prostatic enlargement which was removed 1 year before. The perforations in the pelvis were probably the result of increased back pressure beyond the stricture at the ureteropelvic junction. It is difficult to explain the development of the perforations below the ureteropelvic junction unless these perforations are the result of an attempt of extravasated urine and pus to drain back into the ureter.

CASE 2. K. Z. 53 years of age a housewife, was admitted to the hospital on June 23, 1933, with the complaint of pain in the left upper quadrant. The patient gave a history of kidney colic on the right side in 1926. She subsequently developed kidney colic on the left side in 1928. In March, 1928, a right nephrolithotomy was performed. At this time pyelographic studies also revealed a large calculus present in the lower and larger half of a double kidney on the left side. There was an incomplete duplication of the ureter on the left side with bifurcation at the middle and upper third of the ureter. Operative removal of the left renal calculus was deemed inadvisable because of the marked infection present in both kidneys and the reduced renal function in each kidney. From 1926 to 1933 she received about 75 cystoscopic treatments in the form of bilateral ureteral dilations and pelvic lavages at intervals of 2 to 4 weeks.

For 3 weeks previous to admission the patient had been confined to bed because of marked weakness and severe pain in the left upper quadrant. She also complained of chills, fever, nausea and vomiting. The urine had been very cloudy and at times blood tinged. The patient complained of frequency every hour during the day and nocturia 1 to 3 times, burning on urination, urgency and tenesmus. She noticed a swelling of the left upper quadrant for the previous 2 weeks, which gradually increased in size. She was also troubled with abdominal distention, flatulence, eructation, and constipation.

On examination the patient appeared to be acutely ill and very toxic. There were no evidences of shock or collapse. Cardiac findings were those of mitral insufficiency and arteriosclerotic heart disease. There was a swelling in the left upper quadrant with spasticity and rigidity of the overlying muscles. It was impossible to outline a definite mass in this area. There was exquisite tenderness in the left upper quadrant, left loin, and left lumbar region.

The urine gave a strongly positive test for albumin and microscopically showed a large number of pus cells, an occasional red blood cell, granular casts and organisms which proved to be *Bacillus coli*. The leucocyte count was 9,400 and 75 per cent polymorphonuclears. The blood urea was 70 to 75 milligrams per cent. Intravenous phthalein was reported as 10 per cent for the first hour and 15 per cent for the second hour.

A diagnosis was made of an acute exacerbation of a calculous pyonephrosis involving the lower half of the left double kidney. The signs and symptoms pointed to the presence of an accompanying perinephritic abscess on the left side. Due to the fact that the patient appeared to be critically ill, cystoscopic and pyelographic studies were not carried out. Immediate operation was advised upon admission to the hospital, but the family refused permission until 10 days after admission when the patient appeared to be moribund. She was given a pre-operative transfusion of 500 cubic centimeters of citrated blood. Ten days after admission to the hospital an exploratory lumbar incision was made under spinal anesthesia and a large perinephritic abscess was found surrounding the entire kidney and containing about 3 quarts of a thick, greenish pus which on culture was reported as *Bacillus coli*. The abscess extended up to the diaphragm and down to the pelvic brim, but had not broken its way through the overlying muscles. Extensive drainage of the abscess area was provided. Due to the poor condition of the patient it was decided not to explore the kidney or to attempt to remove the kidney. Following the operation, the patient appeared to rally somewhat, but on the third postoperative day became stuporous and semicomatose and died the following morning.

A partial autopsy was performed which disclosed a double kidney on the left side with an incomplete duplica-

tion of the ureter. The upper supernumerary segment of the double kidney appeared to be relatively normal on gross examination and cross section. The lower segment was a massive multilocular pyonephrosis. The pelvis of the lower segment was covered with a large amount of fibroplomatous tissue which was diffusely inflamed. At a point on the posterior surface of the pelvis corresponding to the mid-portion of the lower segment there was found a perforation from which thick greenish pus exuded. On cross section of the lower segment there was a large branched calculus occupying the extrarenal portion of the pelvis of this segment. There was an area of necrosis about the perforation. The right kidney was of the hypoplastic type and showed arteriosclerotic changes.

The etiological factor responsible for the perinephritic suppuration was a perforation of the chronic inflamed pelvis by a large irregular calculus. In our review of the literature we have not found a similar case of perforation of the wall of the pelvis of one segment of a double kidney. Undoubtedly, the prognosis in this case would have been more favorable if drainage of the abscess had been instituted immediately. The lack of co-operation on the part of the patient's family in consenting to an operation also contributed considerably to the fatal outcome in this case.

CASE 3. J. P. 53 years of age married, male merchant, was admitted to the hospital on May 28, 1933, with the complaint of pain in the left abdomen. The past history was negative except for a chronic gastro-intestinal complaint for the previous 10 years in the form of attacks of cramp-like pain in the left lower quadrant. The patient was admitted to the hospital for a thorough study and during the course of the examination was found to have some pus and red blood cells in his urine. He gave a history of occasional diurnal frequency every 1 to 1½ hours, and nocturia, 1 to 3 times, hesitancy and occasional burning on urination. There was no history of hematuria or renal colic.

Physical examination was essentially negative except for a slight tenderness in the left upper quadrant over the left kidney. A positive left ureteral point was present. The prostate was of normal size.

A complete urological study was undertaken and disclosed (1) median bar formation and (2) left hydronephrosis, third degree, infected and non-functioning. A plastic operation on the pelvis of the left kidney was performed under spinal anesthesia. An elliptical piece of tissue was removed from the superior and inferior aspects of the pelvis and a Heinecke Mikulicz repair was done at the uretero-pelvic junction. The patient made an uneventful recovery. About 1 month after operation a cystoscopic and pyelographic study was made and revealed a marked reduction in the size of the left hydronephrosis with a definite restoration of function in this kidney.

Eighty days after operation he developed a sudden pain in his left loin followed by a chill, nausea, vomiting and fever. Some relief was obtained by an application of heat to his left loin. Four days later he had another chill and was seen for the first time following the operation. At this time an area of fluctuation was noticed in the upper angle of his incision. There was tenderness in this area. There was no history of trauma. A tentative diagnosis of rupture of the pelvis with extravasation of urine was made and the patient was sent into the hospital.

Pyelographic examination revealed dilatation of the left pelvis with an extravasation of dye outside the kidney pelvis. Ninety three days after the previous plastic operation on the pelvis, incision and drainage was performed at the site of the old sinus tract and 50 cubic centimeters of a foul-smelling, sero-sanguinous material escaped. Three days later a left nephrectomy was performed under spinal anesthesia. The patient made an uneventful recovery and was discharged from the hospital with the wound entirely healed.

Examination of the left kidney showed diffuse pyelonephritic involvement of the kidney substance with a diffuse cortical abscess formation, also a marked perinephritis was present. At the ureteropelvic junction, which was the site of the Henckels-Mikulicz repair, there was a very marked narrowing of the mucosa, producing almost complete obstruction. There was a perforation in the line of the suture.

The cause of the perirenal extravasation of urine in this case was the failure of the suture line to hold following plastic repair of the stricture at the ureteropelvic junction and the development of a postoperative stricture and subsequent perforation at this point. Obviously the suture line held for a short time after operation for a pyelographic study performed 35 days after operation showed no extravasation of dye. However it is possible that the suture line was weakened as a result of the postoperative pyelographic study undertaken to check the result of the operation. Intravenous urography for this purpose should preferably have been employed.

TREATMENT

The keynote of success in the treatment of rupture or perforation of the kidney pelvis is immediate operative intervention. The type of operative treatment may be either conservative or radical since no hard or fast rules can be laid down to apply to every case. There are several factors which require careful consideration and which may greatly influence the surgeon in his choice of operative therapy. These factors are: (1) the early recognition of the true nature of the disease; (2) the general condition of the patient; (3) the time elapsing between the pelvic rupture and the diagnosis of the condition and institution of operative treatment; and (4) determination of the pathological condition of affected kidney and condition of the opposite kidney. If the patient has been under observation for some time due to the uncertainty of the diagnosis or to the failure of the physician to recognize the serious nature of the condition, the operative treatment may vary depending upon the secondary pathological complications developing in the course of operative therapy. The final decision as to the type of operation as a very careful and rational pre-operative plan

of therapy may be disorganized by the pathological findings encountered at operation. I.e. extent of extravasation of urine and suppuration in the perirenal tissues, and the presence of a severe disease process in the damaged kidney.

The most important step in the surgical treatment of ruptured pelvis is prompt and adequate drainage of the extravasated urine or pus in the perirenal tissues. This procedure is a veritable life-saving measure as it assures proper elimination of urine and pus from the perirenal tissues, relieves the patient of toxic absorption of urine, fibrin and tissue ferments, enables the patient to regain strength and recover from shock. All other steps in the operative treatment can be postponed or delayed if necessary without jeopardizing the life of the patient.

Occasionally the immediate institution of the drainage of the perirenal tissues is sufficient to effect a cure. It is conceivable that such a favorable outcome may be obtained in the case of a traumatic rupture of the pelvis of a congenitally normal kidney in which the perirenal extravasation of urine is handled efficiently. In such a case, perirenal suppuration is absent or very slight and penneal suppuration is absent or the pelvic fistula closes clear up entirely and the pelvic fistula closes spontaneously. It is very important that the surgeon should expose the entire kidney if possible and make a careful examination of the kidney in order that any additional tears or rupture in the renal parenchyma, pelvis, vascular pedicle and posterior peritoneum are not overlooked or neglected.

The ideal conservative form of treatment combines incision and drainage of the perirenal tissues with repair of the rupture or perforation of the pelvis and correction of the pathological process responsible for the rupture. While this plan of treatment is in keeping with the trend of modern renal surgery toward the conservation of the kidney it is not always possible or advisable to adhere to this type of treatment. In reality there are relatively few cases of ruptured pelvis that lend themselves to such conservative operative therapy. This procedure was employed in 2 cases (Rowland Cowden). In the majority of instances, the extravasation of urine has proceeded on to frank suppuration and the kidney shows signs of severe damage, so that any attempt to save the kidney in the presence of a severe suppurative process in the kidney and surrounding tissues may jeopardize the patient's life or prolong the convalescence unnecessarily. However there is a small percentage of cases in which this type of conservative treatment is recommended and urged. When the patient is operated upon within

a few hours after a rupture of either the spontaneous or traumatic type and the kidney does not appear to be badly damaged by a pre-existing pathological process, and the extravasation of urine is scant and well localized, conservative treatment is indicated and yields good results. This type of treatment is particularly applicable to those cases with small lacerations or perforations secondary to an impacted calculus in the pelvis or upper third of the ureter in which the removal of the obstructing calculus, repair of the pelvic laceration and drainage of the renal bed can be quickly and efficiently accomplished. This type of treatment was successfully employed in 7 cases (Legueu, Mathe and Ovideo Turner Beach, Crane, Mathe, and Wesson). In removing the offending calculus it may be necessary to enlarge the site of rupture or perforation and convert it into a pyelotomy incision which can readily be closed by suturing.

While it may seem to be a logical and ideal procedure to attempt a plastic repair of pelvic laceration at the time of preliminary drainage such a procedure is always difficult and frequently impossible in the presence of an inflammatory and infiltrating process in the perirenal tissues or dense peripelvic adhesions resulting from the extravasation of urine and pus. Experience has shown that the success of plastic operation on the renal pelvis depends upon careful planning and aseptic operative conditions. Furthermore it is folly to attempt a plastic operation on the pelvis without a previous determination of the condition of the kidney or ureter on the affected side either before or at the time of operation since it is difficult to conceive how any form of repair can be expected to hold under pressure proximal to an unrecognized ureteral obstruction.

The radical type of treatment in cases of ruptured pelvis is combined removal of affected kidney and drainage of perirenal tissues, provided the opposite kidney is normal. This type of treatment was employed in 14 cases without a death. Inasmuch as the kidney presenting a pelvic rupture is practically always considerably damaged or totally destroyed by back pressure (hydronephrotic atrophy secondary to calculous obstruction) or suppurative processes (pyelonephritis), nephrectomy assures the removal of the focus of infection and the elimination of the cause of extravasation of urine and pus into the perirenal tissues and the development of unpleasant and serious sequelae can be avoided. In the final analysis this form of treatment may prove to be most conservative from the standpoint of saving the life of the patient preventing postoperative complica-

tions and shortening the period of convalescence. Not only is nephrectomy indicated in those cases of pelvic rupture in which the kidney is destroyed by back pressure or a chronic inflammatory and suppurative process but also in those cases in which the pelvic rupture is accompanied by an associated injury to the vascular pedicle or an extensive and severe laceration of the parenchyma. Nephrectomy should also be performed in those cases in which there is an extensive rent in the pelvis that cannot be sutured as in the case of a large hydronephrosis, or the pelvis has been avulsed from its attachments at the hilum, or the ureter has been completely torn across at the ureteropelvic junction and repair is difficult due to peripelvic inflammation.

Mathe has stressed the importance of performing a two-stage operation consisting of preliminary incision and drainage followed by secondary nephrectomy at a later date in the advanced cases presenting signs of shock, collapse or severe toxæmia. This type of treatment was employed in 10 cases without a death. The exercising of such judgment often is the determining factor in obtaining both a live patient and a good functional result. As many of the patients with ruptured pelvis appear to be debilitated and toxic from the accompanying perirenal suppuration, it is readily understood why primary nephrectomy under these conditions is fraught with danger and likely to terminate fatally. Primary incision and drainage serves to control and minimize the danger of the perirenal suppuration and enables the patient to recover before a secondary operation, either nephrectomy or conservative repair, is undertaken. Furthermore, the urologist may take advantage of the period of convalescence following preliminary incision and drainage to undertake a thorough urological study to determine the cause of the pelvic rupture and plan the operative procedure necessary to correct or remove the causative lesion. In the very sick patients, it is important that the preliminary incision and drainage be done with as little manipulation as possible in order to preserve the natural barriers and to avoid dissemination of the infection.

The choice of the secondary operative procedure to be performed depends upon a variety of possible circumstances which make generalizations impractical. As indicated above, in an occasional case the perirenal suppurative process may clear up entirely and the pelvic fistula may close spontaneously thus eliminating the necessity of a secondary operation. In those cases in which the integrity of the pelvis or the continuity of the ureter or pelvis has been interrupted by partial or

complete circular laceration clitoral stenosis, or destructive process, the pelvic fistula may persist and a conservative plastic operation on the renal pelvis may suffice to effect a cure. However, it is very likely that even under these favorable circumstances, the destructive process in the affected kidney, has impaired the kidney function to such an extent that the improvement in the function of the affected kidney following plastic operation is so slight that infection or stasis soon ensue necessitating subsequent nephrectomy.

Obviously in those cases in which evidence of bilateral renal disease has been previously determined preliminary incision and drainage is indicated pending a more complete investigation of both kidneys. This type of treatment was employed in 2 of 3 fatal cases which were moribund at the time of operation. In cases of ruptured pelvis complicated by bilateral renal insufficiency or bilateral hydronephrosis, temporary pyelotomy or nephrostomy or decapsulation at the time of preliminary incision and drainage may be an extremely valuable measure and may preserve the function of the kidney until some final corrective procedure is carried out.

Occasionally the presenting symptoms may be so strongly suggestive of an intra-abdominal lesion that an exploratory laparotomy to rule out such a lesion was performed (Dodge, Rowland, McAlpine, Hammel) before exposing the kidney through the usual lumbar incision. It is well to point out that infrequently the ruptured pelvis, especially in the spontaneous type, may be accompanied by a peritoneal perforation with peritonitis and it may be advantageous to approach or remove the kidney by the transperitoneal route and at the same time provide drainage of the perirenal tissue through a stab incision in the loin.

The question of anesthesia is an important one. When preliminary incision and drainage is performed in patients who are critically ill or moribund, the operation should be done under local infiltration anesthesia. If the patient's general condition is good and symptoms of shock or toxemia are absent, spinal anesthesia, using 50 to 100 milligrams novocain may be employed with safety as in 2 of the author's cases. Inhalation narcosis with ether whose cardiac stimulative powers are well known should be employed in those cases presenting threatening signs of vascular collapse or showing a low cardiac reserve.

CONCLUSIONS

A review of 64 cases of ruptured pelvis collected from the literature and the author's experience

with 3 personal cases warrants the following conclusions:

1. Rupture of the kidney pelvis proper is a relatively rare condition. The rupture may be of the traumatic or spontaneous (non-traumatic) type.

2. The traumatic type of ruptured pelvis may occur in a congenitally normal kidney or in an acquired inflammatory (chronic pyelonephritic) or obstructive (hydronephrotic) kidney. The rupture is usually the result of direct or indirect trauma exerted against the kidney in such a manner that the physiologically or pathologically distended or chronically inflamed pelvis is jammed against the lower ribs or the transverse processes of the upper lumbar vertebrae as maintained by Kuster. The rupture is usually linear and radial in character. The degree of external violence varies from a crushing injury to an indirect blow in cases of rupture of a hydronephrotic pelvis.

3. The spontaneous type of pelvic rupture practically always occurs in a kidney which is the seat of a chronic pyelonephritic process or whose pelvis is dilated as the result of a ureteral or pelvic obstruction. The most common type of spontaneous rupture is the rupture of the pelvis of a hydronephrotic kidney secondary to an obstruction of the ureter or pelvis by a calculus or stricture. The rupture occurs as the result of a sudden or gradual alteration in the increased back pressure caused by an obstructive lesion in the upper or lower urinary tract. Perforation of the pelvis resulting from pressure necrosis of an impacted calculus is another frequent type of spontaneous rupture.

4. Rupture of a pathologically weakened pelvis may also occur as the result of instrumental perforation or follow the exertion of increased pressure in the syringe method of pyelography. In rare instances, perforation may be due to chemical necrosis following the injection of a strong alkali by mistake during pyelography or renal lavage.

5. The traumatic type of rupture has a greater incidence than the spontaneous type. The traumatic type apparently occurs with greater frequency among the males which may be due to the fact that males are subjected to greater hazards in this age of highly mechanical industries, automobile travel, and competitive sports. The spontaneous type occurs with about equal frequency in both sexes. The traumatic type may have a greater incidence in children due to increased susceptibility of a pathologically weakened pelvis in children to rupture following mild trauma which may be attributed to the persistence of

infantile ptosis and lack of bony protection of the ribs.

6 There is no definite symptom complex or clinical syndrome that is absolutely typical or constantly associated with rupture of the pelvis. The urologist should suspect a rupture of the pelvis if patient gives an antecedent history of chronic pyelonephritis or hydronephrosis secondary to calculus in the pelvis or ureter and presents the following train of symptoms, viz., sudden sharp pain in renal region followed by sudden or gradual swelling or mass in same area, accompanied by chills fever nausea vomiting, and frequently shock or collapse. Signs of collapse may be present in the traumatic type of rupture but absent in the spontaneous.

7 The clinical impression of ruptured pelvis should always be confirmed or substantiated by a thorough urological study including pyelography since this is the only dependable method of diagnosis. The advantages of the gravity method of pyelography and Wesson's combined method of intravenous urography and ureteral catheterization and the dangers of syringe pressure pyelography cannot be too strongly emphasized. In the extremely toxic and debilitated patients, retrograde pyelography is contra indicated but intravenous pyelography can be substituted without fear of producing any unpleasant symptoms or complications.

8 Successful treatment in cases of ruptured pelvis is directly dependent upon an early diagnosis and immediate surgical intervention. The ultimate choice of the operative procedure can only be made at time of operation and must take in consideration the general condition of the patient, pathological condition of the kidney as seen at operation, and the extent of the extravasation of urine or the suppurative process in the perirenal space.

9. Treatment may either be conservative or radical. The conservative procedure is essentially incision and drainage and if possible, correction of pathological processes responsible for the rupture and repair of the pelvic laceration. The radical procedure is nephrectomy provided the opposite kidney is healthy. In the very toxic and debilitated patients treatment should be carried out in two stages, viz., preliminary incision and drainage followed by nephrectomy or conservative repair at a later date.

FRACTURES OF THE HUMERUS END-RESULTS FROM TREATMENT

RALPH K. GHORMLEY M.D. F.A.C.S. ROCHESTER, MINNESOTA
Section in Orthopedic Surgery The Mayo ClinicAND
RUDOLPH J. MROZ, M.D. ROCHESTER, MINNESOTA

THE following review of end-results from treatment of fractures of the humerus covers a 5 year period from January 1 1936 to December 31 1940. All cases of fracture of the humerus encountered at the Mayo Clinic during this period are reviewed here. For the purpose of tabulation we have divided these cases into 8 groups.

Our classification does not conform to the one usually given. In most classifications supracondylar fractures are all grouped with "fractures of the elbow" and in many of such classifications the elbow and head of the humerus are fractures of the neck and head of the shoulder. We have grouped with fractures of the shoulder fractures with fractures of the supracondylar fractures not attempted to divide supracondylar fractures into the usual groups but have separated fractures of the single condyles, epicondyles, and the capitulum as well as those of the trochlea. This grouping conforms to anatomical types and presents interesting comparative features, particularly in regard to the incidence of late nerve complications associated with injuries about the elbow.

The predominance of old fractures of the shaft will be seen in Table I. This, of course, is a fracture that is seen frequently but at the same time it must be realized that it is a difficult fracture to treat and one that leads to many unsatisfactory results. This predominance is partly accounted for by the frequent injury of the musculospiral nerve, a complication that in many cases leads to a major complaint, and the frequency with which non-union is also encountered combined with injury of the musculospiral nerve to make up the majority of cases in this group of old fractures of the humerus.

In Table II we have listed the cases of old fracture of the shaft of the humerus according to the main complaint on admission, that is, the chief reason why patients sought further medical advice and treatment. Non-union makes up the largest of these groups, and because of the frequency with which it is encountered in fractures of the humerus it would be expected to be the most frequent complaint. Taking the cases of non-union alone, and adding to them the cases of non-union with nerve injury and non-union with

infection, we have a total of 55 cases, or about 65 per cent of the entire group. This group contains a few cases that should be classed as delayed union. We have considered all cases that were seen more than 2 weeks after the time of injury as old fractures. There are, therefore, a few cases that should be classed not as delayed union or non-union but simply as cases of recent fracture with malposition.

Some few patients were given reassurance that their arms would be all right, and this satisfied them. There were 2 pathological fractures in the group one resulting from a bone cyst and the other almost certainly from parathyroid hyperfunction with osteitis fibrosa cystica. One case was a medical problem only the patient coming with her lawyer rather than with her physician.

This group of cases represents, of course, a great many failures of treatment elsewhere. From the study it is hard to account for all of these failures many perhaps, were due to poor reduction, some, to infection and so forth. It seems to us, however, that probably the most common cause of failure was too short a period of fixation or inadequate fixation. The humerus is probably the most difficult bone in the body to fix adequately and securely and it is apparent from the study that this is a common cause of failure in its treatment.

Besides the original surgical treatment in the cases set forth in Table III in many cases there had been operations for non-union. In all, 44 patients had had surgical operations prior to their admission to the clinic. Several of these patients had had multiple operations performed as many as 4 in some instances. In all, 78 operations had been performed in these 44 cases, or an average of 1.8 operations per patient.

The problem presented in these cases, therefore, varied considerably. The non-union group presented the most important problem from the standpoint of the orthopedic surgeon.

In the majority of cases listed in Table II treatment consisted of massive bone graft, as described by Henderson. Very little modification in this technique has taken place since that time.

TABLE I—FRACTURES OF HUMERUS 1926-1930

Total	89

In several instances, where sequestra were present or where there was any sort of infection it was necessary to do one or two preliminary operations to prepare the bone for the graft. The removal of foreign fixative substances, such as bone plates or Parham bands may be done at the same time that the bone graft is applied, provided no infection is present. When infection is present, it should be cleared up and should be quiescent for a period of 6 months to 2 years before a bone graft operation is undertaken.

Care must be exercised to get the ends of the ununited bone to fit together as accurately as possible. One must also drill the eburnated ends so that a sufficient opening is made into the marrow cavity to allow new circulation to be established through the eburnated bone. The graft is fitted as accurately as possible to the surface of the bone and held with a clamp until beef bone screws can be inserted to hold it in place. A plaster-of-paris body-cast with the arm in 45 degrees abduction is applied. Much operative time can be saved by applying the body portion of the cast prior to operation.

At the end of 3 weeks the wound should be dressed and the sutures removed. The period of fixation with the plaster after this varies considerably. In most instances union will be firm enough at the end of 3 months to allow removal of the cast and the use of a sling. However, one must be guided by examination of the part, both by roentgenogram and by physical examination. Too long a fixation period is far better than one that is too short. In a few cases it may be safe

to change from a plaster-of-paris cast to an aeroplane splint at the end of 8 weeks. However as a rule it is much safer to continue with the plaster cast until the end of 3 months at least. Rehabilitation should be carried out only after one is certain that union has taken place. Massage and active exercises should be the modes of re-establishing movement of the affected part.

In cases where infection was the predominating cause of complaint treatment was carried out according to the stage of the infection, and when sequestra were present they were removed surgically. In general a modified Orr treatment was used for osteomyelitis (Table V) that is thorough surgical preparation of the wound, using vaseline gauze packs as dressings. These were usually changed once a week to prevent the odor from becoming too offensive.

The cases summarized in Table VI present nerve complications as the most important physical finding and make up a large group they will be dealt with more fully in another paper. This table is inserted here to complete this statistical study.

As we have stated before all fractures under 2 weeks duration have been considered new fractures. In the group in Table VII there were 35 of these fractures over the 5 year period, and the

way these were treated and the results obtained are indicated in the table.

In the consideration of the treatment of acute fracture of the shaft of the humerus, several facts are of importance in coming to a conclusion as to the type of treatment best suited to the case. Simple transverse fractures are best held by some

We have used the terms good, fair, poor and unknown. As good results, were classed all those cases in which firm bony union without deformity and with practically no limitation of motion were obtained. Under fair results were classed the cases in which firm bony union followed but with some deformity or limitation of motion. Under poor results were classed the cases in which union was not obtained or in which there was some impairment of function or deformity sufficient to make the patient seriously handicapped by the result. Unknown results were classed the cases in which the patient was unable to give results. It should be noted also that in many cases where no treatment was recommended, particularly in the case of old fractures without any prospect of improvement, no follow-up was attempted.

form of internal fixation, either a bone plate or a beef bone screw. In many cases it is extremely difficult to get enough engagement of the fragments without internal fixation to hold the fracture either in a cast or in an acroplane splint. Oblique or spiral fractures are more easily held in most instances, but excellent position may be obtained by the use of some form of internal fixation, either a beef bone screw or a Parham band.

As will be seen in the table in most cases treatment consisted of either a cast or an acroplane splint with traction. Often when a cast was used, some type of traction was also used making a fixed traction type of support. When traction is used it should always be checked carefully with the roentgenogram to prevent the fragments from being pulled apart. Comminuted fractures of the humerus must always be considered most favorable for such treatment because of the difficulty in getting sufficient fixation by any form of internal fixation.

In the 2 cases in which the patients died, there were severe multiple injuries, and fractures of the humeri were merely incidental to the cause of death. Fractures treated with Velpeau bandages were green stick fractures without enough separation to require any additional fixation. "Red traction" is shown as having been used in only 1 case. As a matter of fact, it was used in a considerable number of cases preliminary to casts or

to aeroplane splints in the more severe injuries it is a necessity. In fractures of the humerus with some over riding or deformity, bed traction will be found very useful in reducing the deformity and improving the position. In cases of severe swelling in which rest is needed it is a practical method of obtaining correction of the position and absolute rest in bed at the same time.

One case of fracture of both humeri is listed. These are difficult cases in which to secure proper fixation. The use of the aeroplane splint is difficult and oftentimes impossible. A double cast is the most satisfactory fixation, provided one gets accurate replacement. We feel that in these cases, where conditions permit, internal fixation of at least one bone will give the best results. Bed traction cannot be continued in these cases for over a few days at a time.

In many ways the cases listed in Table VIII are the most difficult types in which to obtain satisfactory results. Old stiff shoulders especially those with dislocation or deformity, offer about as unfruitful a field for obtaining successful results as anyone can imagine. However, in many instances marked improvement can be obtained with persistent and skillfully applied physiotherapy, particularly with active and passive

movements. Fractures treated by open reduction with beef bone screws were comparatively recent ones in which reduction could be accomplished. The 2 cases in which excision of the humeral head was done were old fractures of the neck with dislocation of the head. These are without doubt the most unsatisfactory cases of all for successful treatment. Excision of the head of the humerus does not give a good result. It does, as a rule, however relieve pain, and it may relieve pressure on the nerves in the axilla, thus preventing or minimizing the secondary nerve changes that often take place.

A group of 6 cases of fracture of the greater tuberosity are included in this table. Unless marked displacement takes place in these fractures, no special attempt at reduction is necessary. Some advocate abduction of the arm by the use of an aeroplane splint to prevent displacement of the fragments by the pull of the supraspinatus and infraspinatus tendons. Unfortunately, in this particular group we were able to follow only 2 cases in both of which there had been attempts to improve the movement in the shoulder by manipulation. This is a procedure of value in some cases, but we must emphasize the fact that

it must be used with a great deal of care in the treatment of old fractures, because of the danger of pathological fracture when atrophy through disuse is marked.

In the group in Table IX, we again return to the more acute fractures, and we have tabulated the fractures of the surgical neck. As will be seen in this table, the most frequently used type of treatment was the acroplane splint. In these cases a splint without traction should be used. It should be carefully fixed with adequate support to hold it up into the axilla. At the clinic, we make each splint to fit the individual patient. When much malposition or displacement is present, manipulation under anesthesia is the routine before application of the splint. Where satisfactory reposition of the fragment cannot be obtained, we feel that open operation is indicated and the most useful form of internal fixation has been the beef bone screw. In some cases no internal fixation is necessary. Good alignment can thus be obtained and the results have well justified the means. No poor results were obtained in any of the fractures treated by open reduction. In estimating these results we have only listed as good results those with union without deformity and with practically a normal range of motion. Those with fair results included the cases in which union was obtained but in which normal motion

was not recovered, although in most of these there was sufficient motion to allow use of the shoulder.

It will be noted in Table X that in these cases open reduction did not produce as good results as in fracture of the surgical neck. Usually fracture of the anatomical neck presents a much more difficult problem because of the small size of the proximal fragment. When severe displacement occurs, however, it is often impossible to obtain satisfactory reduction by manipulation and open methods must be resorted to. These types are usually more serious and are doomed to a very unsatisfactory result if left alone.

Strangely enough the 4 fractures of the greater tuberosity were each treated in a different manner. All the results were satisfactory where final reports were available, which goes to show that any method of treatment that is carried out carefully may produce good results in this type of fracture.

One fracture of the lesser tuberosity and one pathological fracture in a case of giant cell tumor of the head of the humerus are included in the list and need no comment.

Total	8	4	2	

The group of cases in Table VI represents a type of fracture in many ways as difficult to treat as old fractures of the head and neck of the humerus. In fact, this type may be regarded as worse because it is with these fractures that Volkmann's ischaemic paralysis occurs and in many of the cases there are complicating injuries of the ulnar nerve in addition. No special form of treatment seems to be applicable, and each case is a problem in itself.

We have divided the cases according to those in which the chief complaint was of deformity and those in which it was of limited motion. Arthroplasty in these cases does not offer a great deal, if we are to judge by the results obtained in this group. It should not be entirely condemned, however, as we have seen occasional good results from its use. Attempts to correct the deformity except in fairly recent cases usually meet with unsatisfactory results. Again, skillfully handled physiotherapy is the most useful method of treatment. We do not feel that manipulation in these cases offers much. We have occasionally seen cases where numerous manipulations have been carried on over a period of several weeks, convalescence. Usually the results are not good.

The group of cases of Volkmann's paralysis presented in Table VII is fairly representative of results in such cases. In 2 cases in which treatment consisted of Jones' ischaemic paralysis splints and physiotherapy there was some improvement. In 2 cases in which tendon plastic operations were done there were fair results. The degree of success in these cases is inversely proportional to the severity of the deformity and paralysis.

The end-results in this group of new supra condylar fractures (Table VIII) emphasize the fact that adequate early treatment may prevent many poor results. We have 3 essential things to consider in this group (1) the reduction of the

fracture, which is of the utmost importance and should be accomplished in as short a time as possible (2) the hæmorrhage that may take place, causing a swelling which must always be considered a potential source of trouble, particularly because of the possibility of development of Volkmann's ischaemic paralysis and (3) the type of fixation, which must not be constricting enough to cause any further impairment of circulation and must not cause compression of the musculospiral nerve.

The need for adequate early reduction and proper fixation is recognized by all. When there is marked swelling, however, as a rule something must be done to relieve it. Elevation of the arm may be used but it is a slow method and for this reason, somewhat dangerous. We have aspirated hæmatomata of large size as a means of reducing the swelling. The other alternative is open reduction, which of course evacuates the blood clot and relieves tension so that much of the danger of ischaemia is averted. In difficult cases with marked swelling we feel that it is the choice method of treatment, provided facilities are at hand for carrying out careful bone surgery.

The choice position of fixation in these cases is acute flexion although such a position is not without danger, as has already been indicated. If swelling is great flexion to an acute angle may further embarrass the circulation. A position must be employed in which the radial pulse can be felt. Furthermore, any type of constricting dressing must either be watched carefully or else not used. If adhesive strips are used to hold the angle of fixation they must be placed so as to avoid pressure on the musculospiral nerve. In

many cases a moulded, posterior plaster-of-paris splint is the safest sort of dressing.

Early motion is desirable. But, unless early motion can be supervised by the surgeon himself or by an expert physiotherapist, disappointing results may ensue. In children under proper conditions motion may be begun at the end of 1 week, provided perfect reduction has been accomplished. However it is safer to wait from 10 days to 2 weeks before starting such movement in most cases.

One must not be distressed at slow recovery of movement. Children are often very slow to push their activities to the point of pain. Patience and time will, in most instances, produce excellent results. Impatience, resulting in manipulations under anesthesia, may produce a persistently painful elbow without any improvement in motion.

This group of fractures (Table XIV) has been classed separately because, for the most part, they make up an entirely distinct group. By distinct is meant that they should be distinguished from the usual supracondylar fracture. We found in

reviewing our cases that in many the diagnosis was not accurate when filed, and only by reviewing the roentgenograms were we able to make the correct diagnosis. Fractures of one or the other condyle are almost certain to lead to trouble if not accurately reduced. Two complications must be looked for: (1) an almost certain bony deformity, either cubitus valgus or varus, depending on whether the internal or the external condyle is displaced, (2) tardy ulnar palsy. Of 8 cases of late paralysis of the ulnar nerve, in 4 there were fractures of the radial condyle, in 3 of the ulnar condyle, and in 1 the diagnosis was intercondylar fracture. Accurate replacement of these fragments, then, is of the utmost importance, and in case of inability to get them back into position by closed reduction one should not hesitate to perform open reduction. When no displacement is present, and this is often the case, the problem is simply one of proper fixation. When severe comminution of either condyle or capitellum takes place, the best treatment is removal of the bone fragments.

The group of old cases in Table XV presents an unsatisfactory group from the standpoint of treatment. The reasons are obvious. Severe de-

formities caused by upward displacement of one or the other condyle are very unsuccessfully treated by surgery.

Transplants of the ulnar nerve in these cases will be reviewed in another paper. The fact that among the 22 cases either no treatment or physiotherapy was advised in 14 shows how little could be offered from the standpoint of reconstructive surgery.

SUMMARY

We have reviewed 341 cases of fracture of the humerus seen over a 5 year period at the Mayo

Clinic. These comprise all types, new and old, and are grouped according to anatomical type. Each group is discussed briefly. The old fractures of the shaft offer the most interesting group from the standpoint of bone surgery. Out of 37 such cases, good results were obtained in 84 per cent and poor results in 8 per cent.

ACUTE MECHANICAL INTESTINAL OBSTRUCTION MORTALITY WITH AND WITHOUT ENTEROSTOMIES

BASED ON A REVIEW OF 241 CASES FROM THE RECORDS OF THE COOK COUNTY HOSPITAL
AMOS FEY, M.D. GALESBURG, ILLINOIS, AND WILLIAM R. CUBBINS, M.D. F.A.C.S. CHICAGO

DURING the past 15 years the literature has been filled with accounts of the value of enterostomies advising their performance when in the least doubt of an obstruction and claiming marvelous results. These claims have not been made with any qualifying statement that the quoted results can be obtained in certain skillful hands, but have been broadcast in such a manner as to lead one to believe that any individual can make an enterostomy in any particular portion of the small bowel with little or no danger to the patient, and with a great certainty as to the ultimate favorable outcome. In other words, that enterostomy is a definite and distinct life saving procedure. Its advocates have apparently forgotten the struggles of Nicholas Senn, Jacob Frank, John B. Murphy and others, to overcome the great morbidity associated with enterostomy, a procedure which had been in use for several centuries, by perfecting a means of end-to-end or lateral anastomosis.

Many writers recommend the making of enterostomies, but do not mention any attempt whatever to relieve the obstruction. The accompanying case histories from Cook County Hospital, which have been studied with great care, show the mortality of an acute intestinal obstruction in relation to enterostomies of any kind, as well as the mortality of resections. They also show the great value of an early exploratory operation when there is any doubt concerning an acute intestinal obstruction whether it be complete or incomplete.

The mass of experimental work that has been done upon intestinal obstruction has so many different angles that it would be impossible to attempt to discuss adequately every phase of that problem in this article. We can, however, say with certainty that most of it has been fruitless and serves only to confuse us in our efforts to lessen mortality unless an early operation is performed and if possible the obstruction is also removed.

We have reviewed 241 cases from the records of the Cook County Hospital. From this mass of material we have attempted to extract a few facts that will be helpful in handling this serious surgical emergency without attempting to discuss

every controversial point which would lead us away from clinical cases to an involved discussion of the theories and experimental work.

The case records reviewed cover all cases filed under the head of "Acute Mechanical Intestinal Obstruction" during the years from 1922 to 1931. This does not include strangulated external hernias or chronic obstructions, which are filed separately and which present a somewhat different problem. For the purposes of statistical study only those cases operated upon are included. Cases of obstruction secondary to carcinoma or intra-abdominal abscess are not included because of complications peculiar to this type of case. A few of these cases were not completely obstructed, but all were of the acute type which constitutes a surgical emergency.

ETIOLOGY

For the sake of brevity we shall discuss under etiology only the type of case reviewed. A more complete discussion of the whole subject would properly include adynamic ileus, ileus due to peritonitis, mesenteric thrombosis, and cases mentioned in the preceding paragraph.

The relation of age and sex to the occurrence of acute mechanical intestinal obstruction is shown in Table I. The condition is quite evenly divided between the sexes. After the age of intussusception it decreases in childhood and is evenly distributed throughout adult life. Except that intussusception occurs in infancy usually below the age of 3 years is of little value in diagnosis.

Adhesions, forming bands or kinks, and foramina through which the bowel may herniate, are the most common causes of mechanical intestinal obstruction (Table I). They account for 74 per cent of the cases in this series. It is important to note that 34 or 39 per cent, of these cases due to adhesions had had no previous surgery. Cases due to postoperative adhesions were most common following surgical procedures for intra-abdominal infection. There were included in the pelvic operations, however, 15 hysterectomies which were not associated with known pelvic infection. The miscellaneous operations include gunshot wounds and various operations too infrequent to classify separately.

In the 34 cases due to adhesions not associated with previous surgery the cause was not determined in 23. In the 11 remaining cases in which the cause was determined the frequency and variety of inflammatory insults that are the common cause of adhesions are clearly demonstrated.

Intussusception is the next most common cause of mechanical obstruction, (21 in this series—8.7 per cent). The majority occur in infancy below the age of 2. In the 4 occurring in later years, 2 were due to benign tumors and in 2 no cause was found (Table I).

Internal hernias occurred in 5 per cent of the cases in this series. These are cases not produced by adhesions and the cause of these hernias can not be definitely stated. The most probable explanation is that they were of congenital origin (Table I).

Volvulus occurred in 3.7 per cent of the cases. Many of the cases of volvulus are really due to adhesions and where the etiologic factor seemed solely the result of adhesions, they were classified under that heading. True volvulus not associated with adhesions or previous operative procedures is rare and in this series constituted only 1.7 per cent of the cases (Table I).

Meckel's diverticulum causes obstruction due to either the formation of adhesions around an inflamed diverticulum or invagination and intussusception. As a cause of intestinal obstruction it occurs about as frequently as a true volvulus in this series of cases. Other rare causes are shown in Table I.

That acute mechanical obstruction can be produced by a variety of causes must be kept in mind when making a diagnosis. The fact that no known etiologic factor is apparent from the history and examination of the patient should not be confusing when the other symptoms and physical findings are present.

SYMPTOMATOLOGY

The cardinal symptoms of intestinal obstruction were pain, nausea, vomiting, and constipation.

Pain was usually the first symptom complained of. It was invariably present. Its character is of diagnostic importance. The early pain was probably due to increased peristalsis as the bowel struggled to force its contents past the obstruction. It was intermittent, occurring at intervals which varied somewhat with the type, completeness, and duration of the obstruction. Auscultation will show peristalsis in many cases to be most active at the height of the pain. This type of peristaltic pain is important diagnostically as it is

quite different from that due to peritoneal irritation. The location of the pain was most often in the region of the umbilicus, but did occur in other regions of the abdomen. However, it was not well localized and could not be used as an indication of the location of the obstruction. As distention

and prostration increased and peristalsis decreased, the pain became more generalized and in many cases was less severe.

Nausea and vomiting occurred at or a short time after the onset of the obstruction, the interval depending on the completeness and location of the obstruction. Vomiting increased in frequency as the obstruction became more severe. The character of the vomitus changed and became foul—slowly if obstruction was incomplete rapidly, if it was complete.

Obstipation was as constant as pain and vomiting, but often more confusing in its interpretation and determination. A patient may be constipated before the actual onset of obstruction or the obstruction be so fulminating that the lack of a bowel movement since onset is not abnormal. The determination of obstipation by the use of the enema is a subject about which there is some current controversy. In this series of cases enemas gave valuable information. The results of enemas as an aid in diagnosis may, however, be misleading unless interpreted properly.

Wangensteen has shown in dogs that a bowel may evacuate itself below a complete obstruction after an enema, and has observed the same phenomenon in clinical material. One of us operated for an obstruction 2 hours after gas and feces were obtained by an enema, and found a gangrenous bowel. We have also observed that a bowel may evacuate itself early due to the initial insult of a developing obstruction and thereafter very little if any gas will form distal to the obstruction. It must be remembered that it is probably impossible to tell the exact time when a partial obstruction becomes complete, and that there may be results from an enema in case of a partial obstruction that may rapidly progress to completeness. Enemas were given in 97 cases classified as nearly as possible by the operative findings as complete obstruction. In 86 cases, or 88 per cent, the enema was returned clear or slightly colored; usually poor results was the notation used in the chart. In 11 cases, or 13 per cent, good or fair results were obtained, but in only 2 of these cases was a second enema given which gave a return of feces and gas. In 7 cases classified under "poor or no results, the first enema gave a return of fecal material and gas and the second no results. Results of enemas given were noted in 17 cases classified as partial obstruction. Good results were noted in 10 cases, or 58.8 per cent, and poor results in 7 cases or 41.2 per cent. When the diagnosis is in doubt, a second enema should be given. The records of the enemas did not in every case indicate the results

completely and accurately. Much better information will be obtained if the surgeon is present when the enema is given, rather than relying on the observation of the nurse. It is evident from these statistics that the results of enemas must be properly interpreted if they are to be of value in making a diagnosis of mechanical obstruction. Peristalsis should be present, indicating that the bowel is attempting to empty itself and that diffuse peritonitis is absent. If feces and gas are obtained and the symptoms of distention, pain, and vomiting are not relieved, one may be certain that the obstruction continues and surgery is indicated. Results after an enema are not a contraindication to surgery unless the patient is relieved, and in many cases symptoms will recur requiring surgery. If feces and gas are obtained from the first enema, further enemas will usually be returned without gas or feces if the obstruction is complete or approaching completeness.

PHYSICAL FINDINGS

Intestinal obstruction was not associated with a constant rise in temperature in this series of cases. In those cases without gangrene, 44 per cent were from 97 degrees to 98.6 degrees; 27 per cent were elevated less than 1 degree; 25 per cent elevated from 1 to 2 degrees; and 3 per cent elevated over 2 degrees. Less than 1 per cent were under 97 degrees. Rather surprising was the fact that those cases with gangrene showed practically the same temperature changes. While temperatures over 100 degrees are not the usual finding, a small number of cases had a temperature of from 101 to 103 degrees. These temperatures were only slightly more frequent in those cases with gangrene. A rise in temperature of over 101 degrees occurred in a few cases without gangrene or marked damage to the bowel wall. These may probably be explained on the basis of dehydration.

There was no correlation between the temperature and leucocyte count. The mouth temperature, if taken when the patient is dehydrated and mucous membranes are dry, may give readings lower than the true temperature taken in the rectum. There was a rather constant increase in pulse rate which seemed to have a definite relation to the toxicity of the patient. The respiratory rate increased with the development of distention.

Distention varied with the duration and completeness of the obstruction. Some complete obstructions with gangrene had little distention when high in the intestinal tract or of short duration. Some partial obstructions demanding surgery had no distention.

Tenderness to palpation was present more often than one would assume from the writings on intestinal obstruction in surgical textbooks. Of 214 cases, it was noted as present in 167 and absent in 47. There was no typical distribution of tenderness. In many cases it was present throughout the abdomen. In those cases where a mass was palpable tenderness was most often localized or most marked in the region of the mass.

Rigidity was noted in 41 cases, 20 of which were complicated by the presence of gangrene. The terms 'tenderness' and 'rigidity,' as noted by different examiners, may be somewhat confusing but at any rate they seemed to have been more common than generally expected. We should like to be able to state the degree of damage to the bowel in those cases in which rigidity was noted and actual gangrene was not present, but this is difficult to do from records made by a number of observers.

The most important abdominal finding is increased peristaltic activity. Table II shows the occurrence of peristalsis. In determining the presence of peristalsis, auscultation is the most valuable method. Visible peristalsis was noted in only a few cases. Audible evidence of peristalsis was intermittent and was occasionally missed at first, during a cursory examination, only to be noted at a second examination. In a few high obstructions it was heard only in the epigastrium. In a few cases it was heard in one side of the abdomen and not in the other.

In this series there were 32 cases in which absence of or decreased peristaltic sounds were noted on physical examination and at operation no gangrene or peritonitis was found. Eighteen of these patients died, a mortality of 56 per cent. Comparing this with a mortality of 28.5 per cent for the entire number of obstructions without gangrene, we are impressed with the importance of diminished or absent peristaltic sounds as an indication of bowel injury even in the absence of actual gangrene.

In Table II, the data on absence of peristaltic sounds in gangrene of the bowel are shown. In a few of these cases peristaltic sounds apparently continued a short time after the occurrence of strangulation gangrene. However, in most cases the advent of gangrene stopped the audible peristalsis after a short interval. In other cases with marked distention, peristaltic sounds had ceased some time before the occurrence of gangrene.

LABORATORY EXAMINATIONS

Our observations regarding blood counts are not entirely in accord with statements in current

TABLE II—PRESENCE OR ABSENCE OF PERISTALSIS OBSERVED IN 177 CASES

	Cases Per cent	
Without gangrene	59	100
1. Increased	3	70
2. Present or normal	1

3. Normal		

surgical works which state that acute obstruction is not accompanied by a leucocytosis unless gangrene or peritonitis is present. Such factors as dehydration and in some instances the transmission of infective organisms through the bowel wall before actual gangrene occurs, make the leucocyte count difficult to evaluate. In those cases without gangrene, 61 per cent had a leucocyte count above 10,000 with 27 per cent above 14,000, and a few ranging above 20,000. In cases in which gangrene had occurred 90.5 per cent were above 10,000 and 66 per cent above 14,000. We think it is important to emphasize the fact that leucocytosis is not to be relied upon in determining the onset of gangrene. Of the cases with gangrene 33.3 per cent had a leucocytosis lower than 27 per cent of the cases without gangrene. It appears that the leucocyte count is not as reliable in determining advent of gangrene as the patient's other physical findings.

Urine examinations in this series did not show any typical findings.

Chemical examinations of the blood have not been done in sufficient number to draw conclusions. From a study of the literature on the subject, we feel that blood chemistry determinations have nothing like the value of the patient's symptoms and physical findings in determining the diagnosis and prognosis. Delay in order to make such determination would be inexcusable.

MORTALITY

The mortality of acute mechanical intestinal obstruction has not changed in the past 30 years. The mortality of this entire series is 42.7 per cent. The mortality rate in series of cases by operators in other large hospitals ranges from 23.5 per cent to 60.9 per cent. No attempt is made to compare these rates, for the series would vary as to types of cases included. There have been series of cases reported by single operators with mortality rates as low as 16 per cent. Research regarding the cause of death has added little of value in reducing fatalities.

We are startled to observe that the statistics in Table III do not indicate a higher mortality due to delay knowing as we do the positive danger of delay in the given case. Statistics notwithstanding delay in operation is not excusable. Every case of partial or complete obstruction carries with it the possibility of a damage to the blood supply of the bowel that cannot be determined before operation. In some of the cases obstruction was partial for a variable length of time before becoming complete or producing gangrene. It is difficult or impossible to select the case with which one may safely temporize. Table III also indicates the frequency with which the deaths, in the cases of obstruction that were operated on early are due to strangulation of a loop. It is obviously difficult to draw conclusions as to the increase of mortality due to delay in surgery when this type of case is included in the cases of short duration. If we omit the cases of gangrene and obstruction in infancy we have a mortality of 13.7 per cent for cases of acute obstruction without gangrene operated on in the first 48 hours. There were 46 cases in which delay in surgery occurred because of a diagnosis of partial obstruction. Some of these were cases of several days' duration at entrance, with a history of mild symptoms, presumably they were partial and delay was perhaps justified by that assumption. In other cases, partial obstruction was diagnosed and interference was delayed because results were obtained by an enema, or because there was little distention or the patient had a bowel movement after admission. Seventeen of these 46 patients died—a mortality of 36.9 per cent. In only 4 was there a gangrenous bowel found at operation. The mortality is higher than for all those cases without gangrene (28.5 per cent). In these cases, complete obstruction was not diagnosed even on entrance to the hospital and in many cases was not present at operation, apparently the longer duration, producing severe damage to the bowel was the factor responsible for the high mortality.

Mortality increases in proportion to duration of symptoms in cases of intussusception in infancy. There were 16 cases with 8 deaths. In 10 the duration was less than 48 hours and there were 3 deaths among these. Of 6 cases with a longer duration than 48 hours, only 1 recovered. Obviously intussusception diagnosed and operated upon early should carry a low mortality.

Table IV gives interesting data regarding the use of drainage of the bowel and enterostomy. In these cases draining the bowel at operation and closing the opening apparently did not accomplish the results hoped for. Table IV shows an

TABLE III—MORTALITY ACCORDING TO DURATION

increased mortality for the procedure, which does not seem entirely accounted for by the fact that the cases in which it was used were more serious than those in which the bowel was not opened. A comparison will show that the mortality equals that for resection of a gangrenous loop.

ENTEROSTOMY

In the few cases of obstruction in which enterostomy was done and the obstruction was relieved as well, the mortality again was as high as that for resection and anastomosis for gangrene. It was noted in some of these cases that enterostomy had not drained the partially paralyzed bowel effectively and that distention had continued. In this series of cases enterostomy has not reduced mortality, contrary to the claims of some writers. Enterostomy without relief of the obstruction was done in 8 cases of this series with 8 deaths. From these statistics it would seem that enterostomy does not preclude rupture of a gangrenous loop nor does it restore its viability and apparently it does not prevent the development of gangrene if the obstruction is not surgically relieved.

The results of the treatment of gangrenous bowel also are shown in Table IV. The cases in which gun barrel fistula was done may have been more serious than those in which resection and anastomosis was the procedure used. Admittedly it is difficult to draw conclusions from a series of cases done by different operators, but the mortality of exteriorization or gun barrel fistula is so high in this series that resection and anastomosis seems the procedure of choice except in a very few cases. Gun barrel fistula in this series of cases has not reduced mortality.

Factors in the high mortality of gun barrel fistula were (1) infection of the abdominal wound and peritoneum (2) digestion of abdominal wall (3) secondary operations necessary for closure.

In addition the patients in whom the gangrenous loop was in the first portion of the bowel became exhausted and emaciated from loss of intestinal contents, hence secondary closure was rendered very dangerous. Of the 12 deaths following gun barrel fistula, 5 were in frankly hopeless cases. Nine cases were apparently not more serious than those resected with an anastomosis, yet there were only 2 recoveries. Two of the 7 deaths in those cases in patients not moribund followed attempts at closure of the fistula. 1 patient died with findings of pneumonia. The other deaths were as nearly as could be ascertained from the records, of the usual type occurring in late obstruction.

TABLE IV—MORTALITY PATHOLOGY, PROCEDURE

	Cases	Deaths	Mortality per cent
Entire series	241	123	51.7
Obstruction without gangrene	175	40	22.8
a. Fracture of adhesions or reduction of obstruction, bowel not opened	148	33	22
b. Lateral anastomosis around the obstruction	14	7	50
c. Obstruction without gangrene in which the obstruction was relieved and drainage of the bowel of some type done	26	10	38.5
d. Drainage of bowel with closure	0	0	0
e. Obstruction relieved and enterostomy (ileostomy 5 cases jejunostomy case)	6	4	66.7
f. Accidental perforation of bowel	6	6	100
g. Removal of gall stones from bowel	1	1	100
h. Calcification with removal of adhesions	1	1	100
i. Circumcision with freeing of adhesions	1	1	100
j. Colonostomy with freeing of adhesions	1	1	100
Obstruction with gangrene	66	83	125.8
k. Resection and anastomosis	3	10	333.3
l. Enterostomy or gun barrel fistula	14	1	7.1
m. Moribund—died on table—no procedure attempted—etc. (In no case was the gangrenous bowel removed)	3	3	100
n. Localized gangrene due to bleed with no respiration of gangrenous segment	1	1	100
Recovery			

PATHOLOGY AND CAUSE OF DEATH

The clinical facts in this series of cases are explained best on a mechanical basis. Death results from damage to the bowel wall due to distention and strangulation. The exact manner in which death occurs is still in doubt, but the pertinent and essential facts are that it follows decreased viability of the bowel. Dragstedt has shown the importance of the factor of infection in a closed loop and many patients die with perforation of a gangrenous segment and general peritonitis. The necrotic loop may be toxic in itself when exposed to the absorptive properties of the peritoneum. Wangenstein has shown that in experimental obstruction there is very little absorption from the obstructed bowel and that the contents proximal to the obstruction are not more toxic than the contents distal to the obstruction. Toxicity from release of the contents of an obstructed loop

into the bowel distal to the obstruction was not observed in this series.

Much has been written about sodium chloride loss as an important factor in causing death from acute mechanical obstruction. In accordance with this theory administration of hypertonic saline has been advocated. Experimentally loss of chlorides has been shown to be a more important factor in high obstruction. Hypertonic saline has not been given in a sufficient number of cases in this series to warrant an opinion as to its usefulness but we wish to point out that in 95 per cent of 147 cases the location of the obstruction was in the ileum, or lower. Moreover while adequate amounts of physiological salt solution have been given in most of these cases after they entered the hospital we are impressed with the relation of mortality to evidences of actual damage to the bowel. In so called simple obstruction mortality increased with distention and with the absence of peristalsis and the usual sequence of events if operation is delayed is distention, absence of peristalsis, impaired viability of the intestine, with all the characteristic findings of peritonitis developing and death. In addition to the clinical evidence of these facts the following postmortem records are further evidence of their accuracy.

Autopsy findings are noted in 11 cases. Two cases were not operated upon. Both had a fibrinous peritonitis without actual gangrene. In 1 case there was also a lung abscess and pneumonia. Five cases at operation showed varying degrees of distention and congestion of the bowel. In all 5, release of the obstruction was the only operative procedure. In 3 a diffuse peritonitis was found in 1 bronchopneumonia and in 1 pulmonary embolism. In 3 cases intestinal anastomosis was done at operation and at postmortem examination a diffuse peritonitis was found. In 1 case a massive gangrene with numerous adhesions was found at operation and no procedure attempted. The postmortem examination showed a mesenteric thrombosis. While definite conclusions cannot be drawn from such a small number of cases yet these few autopsy records emphasize that actual damage of the bowel is the primary cause of death in intestinal obstruction.

From a study of these cases it seems that the essential factor in lowering the mortality of acute mechanical intestinal obstruction is the prevention of damage to the intestine from distention and the pressure of strangulation. Here once more applies the oft repeated exhortation to early diagnosis and prompt surgery—and may we add a word for the importance of skillful technique.

The measures which failed to emphasize or have allowed one to forget these needs have not produced results.

CONCLUSIONS

1. Enterostomy, drainage of the bowel, and gun barrel fistula have not reduced mortality in this series of cases as a matter of fact, those treated by these procedures show a very high mortality. We believe that a fistula, while it does have merits in certain cases, must be justified by careful consideration of the entire case before it is performed. Otherwise, it may increase instead of decrease the chances of death.

2. Simple obstruction without actual gangrene when delay has resulted in marked distention and absence of peristalsis, gives physical findings and mortality similar to that of gangrene due to strangulation.

3. The classification of obstruction into the strangulation type with gangrene and simple obstruction is difficult clinically and dangerous if it leads to delay in surgery.

4. Distinction between partial obstruction and complete obstruction is also difficult to make and delay in operating for partial obstruction leads to marked increase in mortality.

5. Many cases of obstruction occur from causes not apparent from the patient's history and physical findings.

6. We believe that an adequate enterostomy proximal to the resection of an obstructed and injured area will prove to be of great value.

7. Clinical study and autopsy findings show that mechanical damage to the intestine from distention and strangulation causing gangrene and peritonitis, or peritonitis before the development of actual gangrene is the usual primary cause of death in acute mechanical intestinal obstruction. However in addition to these pathological changes, one must never lose sight of the marked dehydration which is uniformly present in all cases of obstruction. In our opinion, the restoration of the body fluids with isotonic salt solutions, when administered by intravenous and subcutaneous methods, is a life saving procedure.

SPONTANEOUS RUPTURE OF THE COMMON BILE DUCT

A SEQUEL OF CHOLEDOCHOSTOMY

WILLIAM L. WOLFSON, M.D. F.A.C.S. AND DAVID R. LEVINE, M.D. BROOKLYN, NEW YORK

RUPTURE of the common bile duct is an unusual accident. Either it is caused by trauma or it is spontaneous in origin, the trauma being the usual cause.

It has become increasingly frequent to interrogate the common bile duct by the direct method of incision and probing to obtain accurate information from within the channel, rather than to rely entirely upon an appraising eye or a palpating finger examining the outside layer and wall of the main biliary tube. Owing probably to the more numerous searches and intubations of the duct, we have had occasion to deal with 3 instances of duct rupture in the past 4 years. They have all followed choledochostomy. Our experience with the first case enabled us to make a pre-operative diagnosis in the 2 other cases.

The cases are reported in some detail because they depict a distinct clinical entity which may be recognized. We also offer a few suggestions that may help to prevent this grave complication.

REPORT OF CASES

CASE 1. I. F. aged 55 years, white female, had frequent attacks of gall-stone colic beginning 35 years ago. A gall bladder with calculi was removed 15 years ago. Following the operation, the pain recurred as before. During a very severe seizure of biliary colic associated with jaundice, the patient was admitted to the hospital and operated on (June 5, 1933). A choledochostomy was performed, a number of calculi in the common duct were removed, and a T tube was inserted. The postoperative course was uneventful; the jaundice cleared rapidly and the tube was removed on the twenty-fourth day after operation (June 27, 1933).

The patient was home and well for 10 days, when she had an attack of cramp-like pains in the abdomen radiating nightly to the right of the interscapular region, associated with epigastric distress, belching and rectal tenesmus, but without vomiting. This attack lasted for 3 hours. Following this episode, there was another seizure several days later which was more severe and of longer duration. This was accompanied by marked abdominal distention and regurgitation. The stools were large and foul smelling. One week following this second attack, the woman again suffered from excruciating cramp-like pains in the epigastrium, radiating to the right side and associated with nausea and vomiting. She was then immediately readmitted to the hospital (July 25, 1933).

Physical examination on admission. The patient was acutely ill, prostrated, asthenic, with a marked malar flush. The tongue was dry, the abdomen rigid. There was a sense of fullness in the right side of the abdomen with exquisite tenderness at the level of the umbilicus on that side. No fluid wave or shifting dullness was demonstrable. White blood count, 10,000 leucocytes per cubic millimeter of blood with 78 per cent polymorphonuclears. The urine showed albumin, graded 3 plus, red blood cells, and granular casts.

Temperature was 102 degrees F. The pulse rate was 100 per minute. Respirations were 22 per minute. An operation, with spinal anesthesia, disclosed an abdominal cavity filled with foul smelling blood. Biliary fluid which contained shreds of necrotic tissue. After the field was aspirated, a rupture of the common bile duct was visualized. Intraductal calculi were felt, but the condition of the patient precluded any attempt to remove them at the time. Three Penrose drains were inserted into the subhepatic area. The postoperative course was uneventful until August 14, when the patient had another attack of pain. A few months later, she was operated upon again for relief of common duct obstruction, and the calculi felt at the previous operation were removed. This time a drainage T-tube was left *in situ* for 7 months.

It is of interest that this patient was operated upon years later for a perforating jejunal ulcer for which a gastrectomy was performed. No ulcer was present at any of the previous operations.

CASE 2. R. B. aged 26 years, white female, gave a history of numerous attacks of biliary colic of 4 months' duration. During the last of these attacks she developed jaundice. On May 9, 1933, the operation notes revealed that the gall bladder was chronically inflamed, but non-calculous. The common bile duct was dilated and contained a cast of thick mucoid material. A choledochostomy was performed, followed by a choledochostomy, a straight rubber catheter being used for drainage. The postoperative course was uneventful, and the tube was removed on the eleventh post-operative day. The external wound was closed by June 7. Four days later the patient experienced a sudden attack of pain in the abdomen and back, and vomited undigested food. There was no constipation. Following this seizure, she was re-admitted to the hospital.

Physical examination. There was disclosed a healed upper right rectus scar and a rigid abdominal wall which was tender throughout. There was impaired resonance with distant breath sounds at both lung bases. Tenderness was definite in the left costovertebral angle. Icterus was noted. The temperature was 102 degrees F. The pulse rate was 108 per minute. Respirations were 22 per minute. White blood count 16,000 leucocytes with 65 per cent polymorphonuclear cells. The urine showed a faint trace of albumin and bile. The blood chemistry was normal. A diagnosis of acute pancreatitis was made and expectant treatment was advised. A roentgenographic study revealed that both diaphragmatic cups were obliterated by some subdiaphragmatic collection. The temperature mounted to 104 and 105 degrees F. The diagnosis was changed to that of spontaneous rupture of the common bile duct. The abdominal cavity was opened, a local anesthetic being used, and was found to be filled with bile and pus. When the field was suctioned off a rupture in the common bile duct was disclosed. Three cigarette drains were placed in the region of the duct and in Morrison's fossa. The postoperative temperature rose to 107 and 105 degrees F. The patient was given transfusions, stimulants, and parenteral fluids, but despite these measures, she died the next day. The culture of the peritoneal fluid showed *Bacillus coli*. No necropsy was obtained.

CASE 3. P. O. aged 42 years, white female, had suffered from biliary colic for 2 years. At times the accompanying

icterus was intense. During an operation on June 19, 1933, a small contracted gall bladder was visualized. The common bile duct was markedly dilated and contained calculi. A choledochostomy was performed with a drainage T-tube. The gall bladder was undisturbed. The postoperative course was uneventful except for a low febrile trend during the first 11 days. The tube was removed 2 weeks post-operatively and the wound healed.

She was re-admitted on August 31, 1933, with a 2 day history of pain in the upper abdomen associated with fever and jaundice.

Physical examination on admission. The patient was acutely ill, with the right upper quadrant of the abdomen tender and rigid, a healed scar in this area, a mild icterus, and moderate abdominal distention. The temperature was 101 degrees F. The pulse rate was 106 per minute. Respirations were 20 per minute. A diagnosis of spontaneous rupture of the common bile duct was made, and an operation was immediately performed under a local anesthetic. When the peritoneum was opened, a large amount of blackish-brown biliary fluid was disclosed. This was suctioned off. The patient's condition contraindicated any further surgical manipulation. Three cigarette drains and 1 gauze drain were inserted. The patient had a stormy postoperative course for the first 3 days, and then made a rapid and complete recovery.

A careful review of the literature has failed to reveal reports of similar cases, but they may be recorded under obscure or indefinite headings. From a critical study of these cases, one is impressed by certain striking and definite characteristics. In brief, the syndrome may be reconstructed in this fashion: A patient with a long history of biliary colic who may or may not have had a previous cholecystectomy, enters the hospital with definite evidence of common bile duct obstruction. The obstruction is relieved, the proof of patency of the duct is established, a choledochostomy is performed, and the patient recovers satisfactorily. After a time, the tube is removed and the draining sinus finally closes. Suddenly, the patient is seized with upper abdominal pains, vomits, becomes distended, is febrile, has a coppery red malar flush, is icteric, and prostrated. Rigidity and tenderness develop in the upper abdomen. Leucocytosis and polynucleosis are present. The abdominal cavity is re-opened, and is found to contain a tremendous amount of admixed biliary fluid.

Acute pancreatitis is the condition most likely to be confused with this syndrome. If it is realized

that a spontaneous rupture of the common bile duct may follow choledochostomies, an immediate abdominal operation will be performed instead of instituting any expectant treatment.

The etiology of the spontaneous rupture of the common bile duct is probably a subacute infectious process at the site of the choledochostomy. With the drainage tube *in situ*, this process is adequately protected. However, when the tube is removed and the common bile duct begins to heal, the granulations are soft and friable, and the exudate covering weak and insecure. Any undue strain on the wall of the duct at this point, because of increased pressure, may cause a rupture. Once the bile escapes into the peritoneal cavity, a widespread peritonitis may develop. That bile causes such a reaction has been proved by many investigators. There is also the possibility that many of the localized subhepatic pools that follow common duct intubations have resulted from a rupture of the duct, the collection being walled off from the general peritoneal cavity.

To prevent such a sequel to choledochostomy, we advocate that the T tube or rubber catheter, when removed, be replaced by a straight rubber tube of the same diameter into the original sinus. This tube is to remain for a long period of time so that effective removal of all infectious material may be maintained until the duct is given adequate opportunity to repair solidly the damage done by the trauma of the operation and the pathological process.

SUMMARY

1. Three cases of spontaneous rupture of the common bile duct are reported following choledochostomy.
2. The diagnosis may be made before operation by the recognition of this definite clinical entity.
3. Immediate operation under local anæsthesia is indicated.
4. The etiology of this complication of choledochostomy is discussed.
5. A means of prevention is suggested.

CONGENITAL CYSTS AND FISTULÆ OF THE NECK

THE study of congenital cysts and fistulæ of the neck is of great interest from an embryological standpoint a knowledge of their development affords the surgeon not only an exact map for the field of action but also an understanding of the many intricate fascinating and rapid transformations of organic anlagen so that he is better able to cope with such tumors. In the main congenital cysts and fistulæ of the neck are divided into two groups median and lateral.

The median cysts and fistulæ have been recognized as having the course of the anlage of the thyroid which was discovered by His who found that in its course through the tongue this tract was always a solid cord never a tube with a lumen. At times high columnar and again pavement cell epithelium was found in the persistent thyroglossal duct and for the most part there were several parallel ducts with much lymphoid tissue around them and clusters of acinous glands. This did not conform with a thyroid tissue origin. Were these larger ducts formed by such acinous

glandular material? The epithelium is of such different appearance that this origin can be readily excluded. In early stages of the thyroid anlage we see a comparatively large lingual duct, the channel which leads from the foramen cæcum into the tongue and from the bottom of which the thyroid anlage develops. This lingual duct is not only relatively large but it has in addition branches which run in part parallel to the main channel. Even in the normal adult the channel leading from the foramen cæcum varies considerably in length. It is rather probable therefore that the thyroglossal duct is an abnormally long and persistent lingual duct. It has been argued that thyroglossal duct fistulæ never have an opening into the foramen cæcum. This is not correct however. It is true that a probe inserted into the fistulous tract is arrested chiefly at the hyoid bone but this is due to a kinking or to a local obliteration which very often occurs at this point. The hyoid receives cartilaginous form in the beginning of the fifth week of embryonal life when the normal thyroglossal tract has vanished. If a duct persists at that time the hyoid may develop behind it, which is the most frequent happening or it may include the channel, or in rare cases may develop in front of the duct. Very frequently the duct is kinked off or entirely obliterated at this point. However in some cases the whole channel could be injected. Takeda could inject the fistula even from the foramen cæcum and found that the injected fluid appeared in drops from the outer fistulous opening. The lymphoid tissue and the clusters of mucous glands accompanying the duct lumina can be

explained as having been drawn along from the surface. The great mass of lymphoid tissue at the base of the tongue called lingual tonsil, reaches anteriorly to the foramen cæcum. A thyroglossal duct which is still present in later life is probably the result of an abnormally long and persistent lingual duct which was drawn downward in the fourth week of embryonal life by the very rapid descent of the thyroid anlage. In the majority of the cases fistulæ are caused in postnatal life by perforation of a pre-existing cyst. An adenoma or a carcinoma may develop from an embryonal inclusion such as described and for this reason it will be worth while to study and make note of the exact site of the earliest beginning of a carcinoma of the base of the tongue, some of them have been found to have originated at the foramen cæcum.

The lateral congenital fistulæ are not as readily and as definitely understood as to origin as are the median ones. In the lateral fistulæ several embryonal structures are possible sources.

The second branchial cleft and pouch were thought to have a part in the formation of lateral fistulæ. This assumption was based on Rabl's demonstration at this location of a very long and narrow channel like formation (Rabl's duct). The assumption that lateral fistulæ originated exclusively from the second gill cleft was not accepted by other students of embryology. They believed that the other clefts, not the second alone, might be the cause of such cysts and fistulæ. Then, in 1912 Wenglowski after a thorough study of a large amount of material, published a report in which he concluded that the thymopharyngeal duct, because of the persistence and elongation of the primary thymus anlage which contains a vesicle was the sole structure responsible for the production of lateral cysts and fistulæ. The thymus is a derivative

of the third pharyngeal pouch. This view prevailed for a long time and undoubtedly in many cases, perhaps even in the great majority, the condition was brought about by such factors. This viewpoint did not remain unchallenged, however, for in 1927 Nylander published an account of his embryological research which led him to contradict Wenglowski's views inasmuch as he did not believe Rabl's decision was applicable in all cases. Nylander claimed that even the majority of the lateral cysts and fistulæ were due to a persistence of Rabl's duct. The surgeon can decide promptly in a given case whether he is dealing with one or the other variety of fistulæ, this is possible through his knowledge of the relation of the channel to the carotid vessels. In early embryonal life the external carotid runs straight upward from the common carotid, both vessels lying in front and mesial to the branchial apparatus. The internal carotid is the axis of the third branchial arch which it traverses from in front backward. Any evagination from the second pharyngeal pouch traverses therefore the space between the internal and external carotids, the internal carotid lying posterior, the external anterior to the fistulous tract. If the fistula involved is of the thymopharyngeal duct type, the tract must lead around the outer side of both carotids because the thymus originates from the pouch underneath the third arch. Future exact observations will have to be made to determine the relative frequency of the two origins mentioned. At present the question is still *sub judice*.

In a field in which rapid transformations take place as in the branchial apparatus with its derivatives many diverse embryonal inclusions are very possible, indeed, several rare isolated cases of fistulæ or cysts from other sources are described in the literature.

Embryonal epithelial remnants, according to Cohnheim's theory are a source of neoplasms

and in the branchial apparatus may give rise particularly to adenoma and carcinoma. A branchiogenous carcinoma of the neck near the bifurcation of the common carotid is not very infrequent. As in cases of carcinoma of the base of the tongue it will be of interest to investigate wherever possible, the exact location of the first appearance of the carcinomata of the tonsillar lodge. They are not so very rare and some of them may be due to a remnant of the lateral structures mentioned.

ARNOLD SCHWYZER

SURGICAL SHOCK

THE modern tendency in surgery is to classify all forms of acute circulatory failure complicating operations and wounds, except organic heart failure under the head of shock. The causes may be grouped under three general heads, namely, disturbances in vascular tone, disturbances in blood volume and disturbances of tissues and tissue fluids. The importance of the first two has long been known but that of the last has come to light only in more recent years.

Disturbances in vascular tone are brought about mainly through the nervous system. There is much uncertainty as to the rôle which they play in the production of surgical shock. Pure psychogenic disturbances may produce marked lowering of blood pressure as seen in ordinary syncope which shows many of the features of the shock syndrome. The systolic blood pressure may drop to as low as 50 or 60 millimeters mercury and slight bradycardia develop with resulting unconsciousness, but the reaction is, as a rule, of short duration. If a severe wound, resulting in pain and loss of blood, is accompanied by such a psychic reaction it greatly increases the likelihood of the development of a prolonged state of circulatory depression and may lead to shock. Af-

ferent impulses resulting from nerve stimulation from wounds and operations have long been held to precipitate shock independent of psychic action by directly influencing the vasomotor centers with consequent lowering of blood pressure. The mode of action has been variously interpreted as an exhaustion of the medullary vasoconstrictor center reflex inhibition of the vasoconstrictor center or stimulation of the medullary vasodilator center and there is as yet no unanimity of opinion.

Neurogenic fall of blood pressure is most definitely seen in connection with operations on the abdomen especially on the stomach and gall bladder in which it occurs in approximately 10 per cent of the cases. The anesthetic may be either local or general. The blood pressure falls during the early part of the operation and in the absence of hemorrhage. The various pathways of the causative afferent impulses that have been considered are the vagi, the splanchnics, the upper lumbar sympathetics, and the intercostoabdominal nerve roots. The reaction has been most frequently attributed to the vagus, but there are important objections to this theory especially since it is impossible to reproduce the condition by all types of stimulation of vagus fibers beneath the diaphragm. There is an accompanying mild bradycardia but the respirations show little change. The reaction passes off as the intra-abdominal operation is completed and has usually disappeared by the time the abdomen is sutured. Ordinarily it does no damage to the patient and unless blood pressure readings are taken the anesthetist and the surgeon may be unaware of its intensity. If the operation is prolonged and complicated by other shock producing occurrences as hemorrhage, it may assist in leading to a marked state of shock. Ephedrine usually causes its prompt disappearance and should be given if the reaction is prolonged.

There is much uncertainty as to whether or not stimulation of the large nerve trunks in other parts of the body ever causes a marked fall in blood pressure when psychic influences are eliminated. Cutting and pinching nerves at operation and electrical tetanization of nerves in experimental animals results in a rise rather than a fall of blood pressure. However, in cases of extreme injury and prolonged and extensive cutting operations where a number of blood pressure lowering factors may be active, it is often impossible to exclude afferent sensory impulses as a contributing agent.

Hyperactivity of the sympatho-adrenal system resulting in prolonged arterial spasm has been considered as one of the causes of shock, and the recent work of Cannon and Freeman supports this view. The eventual effect of the vasoconstriction is to damage the capillaries, increase their permeability, concentrate the blood, and reduce the circulating blood volume. More clinical evidence is needed for acceptance of the view that this is an important cause of surgical shock.

Loss of blood is of course the most important cause of acute circulatory failure and its significance is too well known to warrant discussion here. Suffice it to say that failure to recognize the extent of internal and even external hemorrhage often leads to the erroneous assumption that other factors are responsible for the state of shock. Loss of blood and psychogenic and neurogenic reactions are the three conditions that may bring about rapid fall in blood pressure with the accompanying picture of shock. However, a patient with a tumor of the adrenal medulla (pheochromocytoma) may be thrown into a critical state of high blood pressure and rapid pulse presumably from hyperadrenalinemia by an operation or injury (as a fracture of the hip recently observed) with a fall in blood pressure before the death.

Recent studies have shown that loss of plasma as by experimental plasmapheresis results in reduction of circulating blood volume, concentration, and stagnation of erythrocytes and a gradual fall in blood pressure with accompanying manifestations of shock. Blalock showed that sufficient plasma may be lost from manipulation of the intestines of dogs to create shock, but such an occurrence is rarely a complication of operations on man.

Alterations of the tissues and tissue fluids as a result of local injury or constriction of the circulation may lead to a state of secondary shock. The cause has been considered by some to be a toxin formed in the damaged tissues which enters the blood stream and produces general toxic symptoms. The toxic agent was thought to be histamine or a histamine-like substance in the case of both wounds and limb constriction. Recent experimental investigations have failed to show the presence of a toxic substance in the damaged tissues or circulating in the blood following either trauma or limb constriction. This does not exclude the possibility of the existence of traumatic toxemia. However, these investigations have also shown that as a result of extensive wounds there is escape of plasma or blood, or a combination of the two, into the tissues in quantities sufficient to create a state of shock. In some cases the blood vessels may be torn and hemorrhage may be the main cause of circulatory failure. If the limb is traumatized without tearing vessels the main cause is extravasation of plasma with a resultant blood concentration. The fluid producing the swelling in traumatized limbs has been found to contain as much as 5 per cent of plasma proteins. Prolonged limb constriction results in increased permeability of capillaries and following release, the part swells markedly from the escape of plasma into the damaged tissues. This dislocation of plasma

proteins may result in impairment of circulation and shock that proves fatal before signs of gangrene have had time to develop. Burns and freezing have been demonstrated to produce circulatory failure in the same way. Plasma proteins are gradually poured out into the damaged tissues in such quantities that marked blood concentration and reduction in circulating blood volume are brought about explaining the state of shock which may develop without the assumption of the formation of toxic substances.

Swingle and co-workers have reported that deficiency of adrenal cortex hormone results in increased permeability of capillaries and loss of plasma with blood concentration and serious reduction in circulating blood volume. They assume that this plays a rôle in surgical shock but clinical studies are wanting for substantiation of the view. Prolonged low blood pressure from any cause increases capillary permeability with loss of plasma and

eventually of erythrocytes with irreparable damage. Blalock has recently shown that this holds for hæmorrhage and that after blood pressure has been low from this cause for three or more hours abundant blood transfusion fails to arrest the escape of plasma and blood and to rehabilitate the circulation.

Clinical experience has shown that as long as permeability has not been seriously damaged low blood pressures usually respond to fluid administration—best to blood transfusion but also well to physiological salt solution. But when the permeability has become too great whether from nervous influences hæmorrhage local trauma, prolonged constriction, burns, or freezing the administration of fluids serves to increase the amount of plasma poured out of the circulation either locally or generally or both, and a fatal termination is the almost inevitable result.

D. B. PREMISTER

EARLY AMERICAN HOSPITALS

THE WOMEN AND CHILDREN'S HOSPITAL

BEULAH CUSHMAN B.S., M.D., CHICAGO ILLINOIS

TO write the history of the Women and Children's Hospital one must go back farther than the day when the doors first opened on the modest little dispensary and hospital that has gradually grown to an organization of its present size. One must go back to 1829, to the birth of Doctor Mary Thompson, who as a pioneer woman in medicine, organized the small unit to serve the immediate needs of women and children more or less destitute following the Civil War. She dreamed dreams as she worked tirelessly to realize her ambition—dreams that were kept alive, in spite of many trials finally to materialize into the present organization.

Doctor Mary Thompson was born in New York State, was educated in the East, and came to Chicago in 1863. She had been preceded by two women who had made an unsuccessful attempt to found a dispensary for women and children but their plans had been abandoned. At the time Doctor Thompson came to Chicago there were two hospitals in the city. Neither permitted women physicians to utilize their facilities and one did not accept women patients. At this time the Civil War was at its height. Medical facilities were limited for those not actually engaged in the war since most of the physicians had been enlisted for services on the battlefield. Drugs were difficult to obtain and few people had the money to pay for them. Friends of Doctor

Thompson appealed to her to help alleviate the suffering of the women and children of the city as well as of the many people who had migrated to Chicago from the East. She organized a dispensary and arranged with a group of druggists to provide medicine at reduced prices. Many of these patients, however were unable to benefit by the medical advice and care that she could provide because they in some cases had long distances to travel to and from the dispensary and were not in physical condition to stand the strain. Out of this pressing need, in the winter of 1864-65 the plans for the founding of a new hospital were formed. On May 8, 1865, a building situated at Rush and Indiana Avenue, was opened. It provided 14 hospital beds, a dispensary, and a drug room. During this first year the hospital treated 203 patients. The charge was presumably five dollars a week, but it is recorded that out of the 203 patients only one patient paid in full for her care.

In its second year the hospital had already outgrown its facilities and was therefore moved to a residence at 212 Ohio Street. It was while located here that the hospital met its first opposition. A petition was filed against it as a "nuisance." The original incentive for this move seemed to be that a man wished to rent for a stable the barn of the residence, which was serving at the time as a laundry for the hospital. The

The Women and Children's Hospital

Proposed plan for new hospital

charge was investigated, the health department reported that the laundry was clean and healthy and the institution was allowed to continue.

Three years later the hospital again needed larger quarters, and this time it was established at 402 N. State Street. It remained there until 1871 when unfortunately the hospital was one of the victims of the great Chicago fire. In 5 minutes, according to one dramatic report, the building was burned to the ground. The patients were transferred to another house but they were soon again forced to leave because the fire had spread. All of the material assets of the hospital were wiped out save for two pillows, a blanket and a piece of carpet.

With these remnants, at the instance of the late F. B. Gardner, Mrs. W. G. Davis, and other interested friends, a vacant house was taken at 598 West Adams Street, which was soon carpeted with mattresses and patients from attic to basement. No bedssteads could be had at the time. Here helpless women and children suffering from general sickness induced by fright, exposure to excessive fatigue and fire, followed by cold rains, were given food and medicine. On the 23rd of December, 1871, the Hospital was moved by the Aid and Relief Society to the Barracks on Throop and Harrison Streets. When the demands produced by the fire had ceased it moved in April, 1872 to 157 Center Avenue where it remained until the opening of the earlier building at Adams and Paulina Streets, February 26, 1873. In 1873, in acknowledgment of public service, the Relief and Aid Society gave the hospital \$25,000.00 with which the site at Adams and Paulina Streets was purchased. The commodious house on this site was transformed into a hospital, the small barn on the rear of the lot being used for the Women's Medical School. In 1873 it founded the first training school for nurses in the middle west. In 1885 the hospital moved into a five story brick and stone building specially planned for it. The new building at Paulina and Adams Streets, was opened December 10, 1885 and remained the home of the organization until the opening of the present hospital at Ashland and Maypole Avenues in January, 1939. The present building providing facilities for 100 patients.

In plancing through the records of the hospital one finds many interesting little touches that must have been of great significance to the hos-

pital. Food is frequently mentioned, from which we may gather that the endowment of the hospital was so meager that even its immediate needs had to be met by the generosity of friends. Pillow cases, garments for the patients, quilts, and similar equipment were provided by individuals and groups. Material for bandages was provided by gifts of old linen. The Third Presbyterian Church contributed one and a half gallons of wine.

The present hospital is a very different institution from that formulated out of the needs of Chicago during the Civil War. The hospital's staff is composed entirely of women physicians. It offers surgical, medical, and obstetrical care, maintains a well equipped X-ray department, which is adequate not only to aid in diagnosis but also to carry out treatment as indicated. The hospital also operates the third largest dispensary service in the city. The Emergency Welfare Relief provides a fund for the care of 20 hospital patients and 65 dispensary patients a day. The institution sustains a standard of work that makes it acceptable by the American Medical Association for the training of internes. A home for nurses was maintained from 1873 to 1930.

One of the unique branches of the work of the hospital is The Mother's Milk Bureau organized and established by Dr. Bertha Van Hoesen in 1930. This organization furnishes mother's milk to the hospitals in the city for babies who are undernourished or for some reason do not tolerate the usual artificial formulas. The milk is obtained from mothers who have undergone very complete physical examinations, and whose babies not only are not using all of the milk the mother has, but are also found to be doing well on the mother's milk; they are consuming. The donors and their babies are carefully supervised to ascertain that the mother eats properly and that her own baby is not being sacrificed for the financial remuneration the milk brings. The milk is collected with great care in special food containers, and is never used if more than 24 hours old. The Bureau distributes about 1500 ounces a month, part of that being given away to families unable to pay for it, for the slogan of the organization promises that no baby in Chicago shall die for lack of mother's milk. This department was founded in 1930 and has its distributing center at the Women and Children's Hospital.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

TO us as medical students 20 years ago two textbooks of surgery seemed to stand out from a considerable number of available and popular one volume works because of their conciseness, their clarity of expression, and their stimulating interest. To these, Stewart's *Manual of Surgery* and deQuervain's *Surgical Diagnosis* has in recent years been added a third,¹ which is the best single volume work covering the field of surgery that we have had the opportunity of reading.

The necessity for a third edition of Homans' *A Textbook of Surgery* only 4 years after its introduction to the medical profession indicates how popular it has become in this short period. Many features contribute to this well deserved popularity: the book is first of all, an attractive and pleasing example of the book maker's art: the illustrations are well chosen, carefully drawn, and truly illustrative: they do not detract from the subjects concerned by excessive size and needless emphasis on trivial details: the historical sketches which introduce many subjects provide a background which is both interesting and essential to the student who would truly grasp surgical principles and practice: the bibliographical index is exceptionally complete and ingeniously arranged to enable the reader to find quickly the source of the author's material. Finally and of greatest importance, is the well balanced presentation of the tremendous number of subjects included in general surgery. To have taken the lectures and papers of many different individuals interested in widely separated fields of surgery to have welded them into a homogeneous whole to have filled in the many and extensive gaps untouched by the author's associates, to have omitted so wisely the obsolete material that has been allowed to encumber many of the older books, and to have produced finally a thoroughly interesting, readable and well considered textbook of surgery seems to us an admirable achievement and one that deserves unstinted praise.

With specific reference to the new edition the publishers list on the inside page of the jacket some thirty subjects "which have undergone correction or been newly introduced in the third edition."

The new material in the author's prefatory words, has been incorporated without a change in pagination under the plan that for everything fresh that comes in something stale must go out. We have not been able to recognize the stale that has gone out but have seen many evidences that the author

has labored diligently to include in this new edition the worth while contributions of the past few years.

SUMNER L. KOCH

ANY literary work which reaches its fourteenth edition and which has been translated into seven foreign languages has achieved a position of unquestioned importance. May's *Diseases of the Eye*² made its first appearance in 1900 and for many years has been probably the most widely used text on the eye for general practitioners and medical students, both in the United States and in several other countries. During the past year the seventh British, the ninth Spanish, the sixth Italian, and the third Chinese editions have been issued.

The secret of this wide universal acceptance has been the fulfillment of the original conception of the author to create a book on the eye not for the ophthalmologist but for the student of medicine and the general practitioner of medicine. Theoretical considerations, detailed discussions and descriptions, and the more unusual ocular conditions are carefully avoided or only briefly mentioned. The language is concise, simple, and explicit. There are many excellent illustrations, including two new colored fundus plates.

Much of the material has been rewritten for this fourteenth edition in an attempt to eliminate the obsolete practices usually carried along from one edition to another in works of this kind. The newer treatment of retinal detachment has been ably handled and brought up to date: there have been revisions on anatomy, pathology and ocular motility.

It may be questioned that ophthalmological optics and refraction should be assigned 63 pages in a work of this scope, intended for and used by the man in general medicine and not by the specialist. It is too detailed for the former and insufficient for the latter. Many minor criticisms might be offered on such points as the rôle of the staphylococcus in the production of acute conjunctivitis, the importance of pain as a leading symptom of retrobulbar neuritis, the rather frequent mention of the use of leeches, and similar points not strictly in keeping with modern practice.

The fine points of this book are too numerous for a few faults to outweigh them and with the improvements and revisions of the present edition it should

¹ A TEXTBOOK OF SURGERY. By John Homans, M.D. 4th ed. Springfield, Illinois, and Baltimore, Maryland: Charles C. Thomas, 1925.

² MANUAL OF THE DISEASES OF THE EYE, FOR STUDENTS AND GENERAL PRACTITIONERS. By Charles H. May, M.D. 4th ed. rev. Baltimore: Williams Wood & Co. 914.

continue to occupy first place in popularity among students and practitioners of general medicine.

WILLIAM A. MARR, JR.

THE new edition of *A Textbook of Bacteriology*¹ by Zimser and Bayne-Jones, is remarkable for the extent to which it has been brought up to date. But even more so is the element of fair judgment with which the authors have evaluated the wide variety of recently published articles.

Even the recent medical graduate who examines this book will find evidence of new and major advances in the subject of bacteriology with definite bearing on clinical medicine. The older graduate will note that a veritable flood has passed under the bridge since his day as student of this science.

The authors have taken a definite forward step in selecting and presenting materials so as to indicate the application of bacteriology and immunology to clinical medicine rather than to present the strictly diagnostic aspect. Yet at the same time they have made available a wealth of information which has been adequately digested and correlated so as to elucidate biological principles.

This book has particular value as a reference volume, giving to its reader information published as late as 1934. The material has been fairly judged by the authors and presented in a manner that makes it readily available. As to its use as a textbook for medical students one wonders if the average medical curriculum allots to the course in bacteriology sufficient time for the student to cover adequately the essentials in this book.

The chapters on the bacteriology of milk and water have been eliminated, to provide, as stated by the authors in the preface, space for a presentation of some of the great mass of newly acquired material. One wonders if the time has not come when the chapter on parasitology can be omitted from textbooks of bacteriology and given over to the protozoologist, for parasitology seems in some respects less related to the science of bacteriology than does the bacterial content of milk and water and their sanitary significance.

The recent developments in bacteriology have more prominent place in this book.

The newer infectious diseases as tularemia and undulant fever are more extensively described and discussed than usual.

Among the more recently developed and important fields of immunology bearing directly on clinical medicine is that of the soluble specific substances. This subject is adequately handled, as would be expected since the senior author was a pioneer in this field. Bacteriophage therapy is discussed in the light of recent experimental studies, and its value as a therapeutic agent is questioned. More space might have been devoted to the presenta-

tion and discussion of the experimental evidence on which the authors based their conclusions, since bacteriophage has been so widely heralded as a panacea in the treatment of infections.

In this book the authors have emphasized the facts and established principles of the science of bacteriology. The unsettled and theoretical has been fully presented and different opinions on controversial subjects presented and controversially discussed.

ARTHUR W. WALKER.

THE recent publication of the fifth edition of Professor Folin's *Laboratory Manual of Biological Chemistry with Supplement*² again brings to date a volume outstanding because of the originality and productivity of its author whose methods comprise a large part of the contents. The arrangement is the same as in previous editions, the material designed essentially for class instruction being arranged in a series of ten parts dealing with elementary considerations of volumetric analysis, catalysis and enzyme action, fats, carbohydrates, proteins, urine analysis and metabolism blood, bone, and bile. Wherever possible quantitative methods of study are presented, there being a minimum of purely qualitative experiments.

The discussion (Part 1) of the essential elements of chemical equilibrium, the proper selection of an indicator for titration and what occurs during the titration of an acid and base, is so clearly and simply presented as to be within the comprehension of any non-mathematical student. One wishes, however, that a few simple experiments had been devised to illustrate the principles discussed. The material contained in Part 5 on proteins is devoted chiefly to color reactions and precipitation tests. In view of the amphoteric nature of protein, it seems to the reviewer that a section devoted to colloidal chemistry, or to a few experiments illustrative of the colloidal behavior of proteins could be added with advantage. An experiment on the isoelectric precipitation of protein would acquaint the student with a method in general use in research and industry today. The methods of quantitative urine analysis are introduced in Part 6. Significant changes have been made in the uric acid method which diminishes the interference by polyphenols and other substances. Parts 7 to 10 remain the same as in earlier editions.

Probably the most valuable material of the book is contained in the supplement. The section has undergone the greatest revision. Professor Folin has discussed in detail the various steps in the more complicated procedures of blood and urine analysis where difficulty may be experienced in learning the methods. In the section on urinalysis a tentative colorimetric method for the determination of phenols has been introduced, Lloyd's reagent and carotic acid being used to remove the interfering uric acid. In the section on blood analysis the use of an unlabeled

¹ A TEXTBOOK OF BACTERIOLOGY, WITH SECTION ON PATHOLOGICAL IMMUNOLOGY. THE APPLICATION OF BACTERIOLOGY AND IMMUNOLOGY TO THE DIAGNOSIS AND TREATMENT OF DISEASE. 1934. 10th Edition. By Hans Zimser, M.D. and Kenneth Bayne-Jones, M.D. 7th Edition. New York and London: D. Appleton-Century Co., Inc.

² LABORATORY MANUAL OF BIOLOGICAL CHEMISTRY, WITH SUPPLEMENT. BY OTTO FOLIN, Ph.D. New York and London: D. Appleton-Century Co., Inc. 1934.

blood filtrate originally devised for the determination of uric acid, has been extended to the methods for blood sugar, creatinin, and non-protein nitrogen. The author justifies its use in the following statement: 'Doubtless there is still room for differences of opinion as to whether indiffusible fixed materials of the red blood cells should or should not be included in some of the analyses, but the view is taken here that the inclusion of suddenly disintegrated cell materials does not belong in the determination of the levels at which definite well known materials are being transported to and from tissue. New micro-methods, with but 0.2 cubic centimeter blood have been introduced for the estimation of non-protein nitrogen and uric acid, together with the author's well known micro-method for blood sugar which requires but 0.1 cubic centimeter blood. Explicit directions for the purification of reagents required in these as well as in other procedures, are given.

As in previous editions, the methods for inorganic constituents of urine and blood devised by Professor Fiske and associates, and for total fatty acids and cholesterol in blood plasma by Professor Bloor have been incorporated.

Not only does this volume fulfill its purpose as a laboratory manual for medical students, but it is especially valuable to all engaged in routine blood and urine analysis and research. C. J. FARMER.

THE Cancer Control Organization for Edinburgh and Southeast Scotland was inaugurated on March 2, 1934. The purpose of the organization is the investigation, the care and the control of cancer. The volume reviewed here is the first publication of the new organization and presents a statistical survey of the results of the treatment of cancer in the Royal Infirmary.¹

The introductory chapter consists of the chairman's address by Mr. J. J. M. Shaw. If this small volume contained nothing more than the chairman's address, its publication would have been fully justified. Those who have attempted to pronounce a brief but comprehensive statement of the cancer problem to a mixed audience fully appreciate the difficulty of this task. Mr. Shaw has accomplished this task admirably. The presentation is clear, concise and beautifully composed. The point of view is sound and well balanced. No one who is interested in the subject of cancer control should fail to read it.

Three hundred and thirty three cases of carcinoma of the female breast and one carcinoma of the male breast are analyzed. The radical operation, sometimes combined with radiation, has been the treatment of choice in the operable group. Cancer of the tongue is treated by interstitial radiation.

It is quite evident that one of the important handicaps in the work of this institution is the inadequacy of radium facilities. The radium bomb does not contain sufficient radium to prove an

effective instrument. The minimum must be one gram, preferably it should contain two grams.

The publication contains further statistical data and the methods of treatment of other forms of neoplasm. It is quite evident from this publication that this group is making a sound and intelligent effort to execute modern cancer therapy.

MAX CUTLER.

A REMARKABLE book is *Cirugia Gastrica*.² The author Manuel Corachán, is a distinguished professor of surgical pathology in the medical school at Barcelona and chief surgeon to a large hospital. He has had a large clinical material, and one needs only to glance at the extensive and well chosen bibliography scattered throughout the book to see that he has been a tremendous reader. Remarkable for a European is the fact that he is thoroughly conversant with American contributions as well as with those of his own country France, England, and Germany. The book is beautifully printed on fine paper and it is beautifully bound. It would be a source of lifelong pride to any publisher in the world. The illustrations are many and they are well reproduced.

Particularly remarkable is the lavishness with which good colored photographs have been used. Many of the roentgenographs are particularly interesting because the technique of Berg and others has been used to show the folds of the gastric mucosa.

It is unfortunate that so few American surgeons read Spanish, for there is much in this book to interest and help them. Actually there is no book in English covering the field so extensively or so beautifully as this volume and its companion will do.

A large part of the book is taken up with hints on the examination of the patient. There is much valuable material also on the anatomy, physiology, and pathology of the stomach. There are beautiful colored representations of what can be seen through the gastroscope.

Much space is given, as one would expect to the problems of ulcer and cancer. In addition many pages are given to the discussion of the rarer lesions of the stomach.

The author gives more space to problems of gastritis and gastropnoia than most American surgeons would give. So far as operating for ptosis goes, he points out wisely that even if an operation is done the patient must be treated medically for a long time with rest and an over feeding diet.

About the only criticism that one might make after reading here and there through the book is that the author might well have trusted more to his own experience and wisdom and less to his extensive knowledge of what others have written. The physician or surgeon looking for help is grateful to the man who has prepared a good review or abstract of the literature, but often he is even more grateful for frank statements by a man of wide experience.

¹CANCER—EDINBURGH 914 Published by The Cancer Control Organization for Edinburgh and Southeast Scotland, Edinburgh E. & S. Livingston 1934.

²CIRUGIA GASTRICA By Dr. Manuel Corachán Vol. I Barcelona Salvat Editores 1934 (715 pages).

The second volume is to contain chapters on pre operative and postoperative care, anesthesia indications for and technique of, the various operations on the stomach, rare or disused operations, the stomach that has been operated on, the results of the various operations, and the bad results sometimes obtained after gastro-enterostomy and gastrectomy.

CHARLES H. MAYO
WALTER C. ALVAREZ

THE volume¹ entitled *Foreign Body in Air and Food Passages* by Drs. Chevalier and C. L. Jackson has long been awaited both by the roentgenologist and endoscopist and neither will be disappointed as it fulfills all pre publication expectations. Coming from the pen of the Jacksons it is quite natural and necessary for it to be simple and lucid yet complete in every detail.

The book falls into eight main sections devoted chiefly to differential diagnosis of both radiopaque and radiopaque foreign bodies from an X-ray standpoint although the associated pathology is not neglected. Accompanied by 150 X-ray reproductions with descriptive legend of all types of cases there is very little if anything overlooked. Thus it is very easy to follow the authors through the description of a drowned lung as compared to a pulmonary abscess or what the roentgenologist might expect from the reaction of tissues to foreign bodies of certain chemical or physical properties.

A very valuable chapter is devoted to fluoroscopic endoscopy in which the biplane fluoroscope is used to great advantage.

The book is filled with valuable axioms learned from years of clinical experience and over 3,000 cases of foreign body in the air and food passages. Written from such a large store of material it deserves high praise for concrete knowledge it discloses and its quality will give it more than a temporary success.

JOHN F. DUFF

IN the third edition of Slemmons' book² on the prospective mother changes have been made in many subjects, especially the arrangement of the diet the gain in weight during pregnancy the employment of the X-ray for greater accuracy of diagnosis the rôle of the endocrine glands in the menstrual cycle and the modern methods of anesthesia at the time of birth.

The reviewer has never believed that pregnant women should be told as much of the anatomy and physiology of pregnancy and labor as this book discloses. The smattering of information which the patient obtains is apt to be misapplied and misinterpreted.

Teachers of obstetrics realize how difficult it is for medical students to grasp the normal in obstet-

A HALL OF ROENTGENOLOGY. SERIES OF MONOGRAPHIC ATLASSES. Edited by James T. Case, M.D. Vol. VII.—FOREIGN BODY IN AIR AND FOOD PASSAGES. By Chevalier Jackson, M.D. and Chevalier L. Jackson, M.D. New York: Paul B. Hoeber, Inc. 1924.

THE PROSPECTIVE MOTHER, A HANDBOOK FOR WOMEN DURING PREGNANCY. By J. Morton Slemmons, M.D. New York: D. Appleton-Century Co. Inc. 1924.

rics. What sort of grasp will the layman get in this short course in obstetrics?

The rest of the information is well given.

In the reviewer's opinion all the information a lay woman needs on the subject of the prospective mother could be stated in fewer than 321 pages many obstetricians find a booklet of 16 to 20 pages ample.

To those who do not agree with him, the reviewer recommends this as a good book.

EDWARD L. CONTELL

THE discovery of the sympathetic nervous system by the surgeon has been a recent affair though the neuro-anatomist and physiologist have been contributing for many years to our knowledge of this regulator of our body's internal economy. Like most fundamental discoveries in science the facts set forth by these experimentalists became general property only when it was shown that somehow and in some way the involuntary control over our blood vessels, glands, and viscera might be influenced by various surgical operations.

So rapid was this invasion of a new surgical field that many procedures were advocated which opposed all known anatomical or physiological facts. In truth, it was only after several years, during which the literature was crowded with publications, that surgeons found that many times they did not fully understand one another. So we find them now solemnly emphasizing that by the "sympathetic system" they mean that part of the autonomic nervous system represented in the thoracic-lumbar outflow. Familiarity with the known facts in the beginning might have made surgical progress more sure and perhaps less bombastic.

During the last 10 years claims for the relief of the spasticity of muscles following lesions of the central nervous system have been disproven step by step. Recently the careful reporting of observations upon patients operated upon for vascular diseases of the extremities has added to the scientific data which must be balanced in the final judgment upon operations designed to give much needed relief to unfortunate patients. It is unfortunate that the critical, unprejudiced judgment of the laboratory worker is not always employed by the surgeon in evaluating the results of his operations. Surely it is not enough to say empirically "the patient was benefited better."

Early in their book,³ Gaak and Ross lead one to believe that their evaluation of the surgery of the sympathetic nervous system is to be a critical one. Unfortunately they do not bow to the line throughout for example, their acceptance of Lewis' contention that removal of the sympathetic supply to an extremity does not prevent the occurrence of attacks of vasoconstriction in Raynaud's disease. Careful examination of surface temperature changes properly

"THE SURGERY OF THE SYMPATHETIC NERVOUS SYSTEM. By George E. Gaak, C.M.B., D.B.O., F.R.C.S. (Eng.), and J. Harrison Ross, M.D. (Lond.), F.R.C.S. (Eng.). Baltimore: Williams Wood & Co. 1924.

controlled and of blood volume changes in the fingers will support that view. These are the facts which the surgeon can add which will be of some ultimate value. It is surprising that the authors, after pointing out correctly that the assumption on which periarterial sympathectomy was based is incorrect devote so much space to the subject and do not insist upon an evaluation of the claimed clinical results similar to those employed by Lewis in his study of the results of operations for Raynaud's disease. Again, we read "It would be unwise to advocate this operation (periarterial sympathectomy) in the treatment of Raynaud's disease or thromboangitis obliterans, though occasionally an astonishing improvement may occur in the latter disease."

The strongest argument for periarterial sympathectomy would seem to be the statements that pain of vascular origin is relieved. Certainly, it should be pointed out that not all cases of causalgia can be relieved by such an operation. Inasmuch as the nerve supply to the vessels of an extremity is segmental, and since it has been shown that there is no pathway for afferent painful impulses along the course of the vessels, it is difficult to understand how the pathway is broken unless by chance the operation is performed above the site of the lesion the exact nature or location of which is commonly unknown.

It is disappointing that the battle between their obvious sense of the application of physiological criteria to the results of their operations and their surgical belief that some clinical good must come of an operation for which they have no scientific factual basis, should have led the authors to champion surgical procedures rather than record their results in graphic data which could be interpreted by their readers. For example, does a patient with removal of the periarterial nerve supply to the radial or brachial artery respond to a stimulus of the lumen of that vessel below the site of the operation?

Finally that the authors realize the necessity for keeping an open but critical mind on this entire business of the surgical attack upon the sympathetic nervous system is obvious in their last sentence.

"until more is known about the pathology of the sympathetic system, the place of surgery in the treatment of its disorders cannot be firmly established."

L. D.

THE author of this monograph, Dr. McIver, has presented a remarkably clear and comprehensive picture of the problem of acute intestinal obstruction from both the clinical and experimental viewpoint.¹ It is the best analysis that has yet appeared and deserves a place with the classic papers in this field. The author and his associates have made a very important and fundamental contribution to our knowledge of the cause of death in acute intestinal

obstruction but this achievement has by no means blinded him to the work of others. He is thoroughly acquainted with the voluminous literature and very few worth while contributions have escaped his critical survey. The first section of the book gives a general picture of the disease and a discussion of the underlying pathological lesions responsible for various types of mechanical obstruction. The importance of the level of the obstruction and the condition of the circulation in the mesentery and intestine is emphasized. There is a thorough discussion of the symptomatology and an excellent summary of the changes in the chemistry of the blood and in the body fluids, a field in which the author has made such a signal contribution.

The diagnosis of acute obstruction is based upon the clinical symptoms and upon X-ray examination with or without a barium enema. Laboratory studies are usually of little aid, since changes in the blood chemistry may not be present in some cases, and appear too late in many others. The section on treatment emphasizes the necessity of prompt operative intervention. While the replacement of fluid and restoration of the altered blood chemistry is important, operation must not be too greatly delayed on this account. Decompression of the stomach and the obstructed intestine by means of a duodenal tube with moderate suction is described. The author however wisely reserves judgment regarding the general applicability of this method and is concerned lest its adoption postpone surgical treatment.

The surgical treatment of acute intestinal obstruction is thoroughly described and the usefulness of enterostomy is emphasized. The sections on pre-operative and postoperative treatment and the methods of handling high intestinal fistulae and other similar complications are especially instructive.

The last section contains an excellent critical summary of the experimental work that has been done to determine the cause of death. The relative significance of dehydration, due to loss of the various digestive secretions, and toxemia due to absorption from the proximal intestine, in obstructions at various levels in the gastro-intestinal tract and with varying degrees of circulatory interference to the bowel wall is ably presented and the conclusions drawn are logical in the light of present knowledge. Every general surgeon and everyone interested in the problem of intestinal obstruction from the experimental standpoint should read this book.

LESTER R. DRAGSTEDT

THE first edition of Stokes' excellent monograph on syphilology was published in 1926. In the second edition,² the book has been enlarged and 15 of the 23 chapters have been rewritten. A new chapter on relapse and progression is another improvement.

The first edition had, as a definite aim, the presentation of the subject to the completely uninitiated

LATE COMPLICATIONS IN IRRADIATION TREATMENT OF CANCER OF CERVIX¹

QUITMAN U NEWELL, M.D. F.A.C.S. AND HARRY S. CROSSEN M.D., F.A.C.S. ST. LOUIS, MISSOURI
From the Department of Obstetrics and Gynecology, Washington University School of Medicine and Barnes Hospital

THE effective treatment of cancer of the cervix uteri necessarily carries considerable risk to the patient. The risk is less with irradiation than with operation, but irradiation carries definite dangers. The serious responsibility and difficult problems in the use of radium in this situation are not generally appreciated. If the dose is too small, the distant cancer cells survive and the patient dies of recurrence. If the dosage is pushed to the point of causing devitalization of the outlying cancer cells, there is danger of irradiation injury of the rectum and bladder and the ureters.

To give the patient the best chance of cure and at the same time to hold local injury to the minimum require expert study of the particular conditions present in the pelvis in each case, and a careful adaptation of every means to the administering of the maximum dosage permitted by those conditions. In this work thorough knowledge of pelvic anatomy and pathology with training and experience in accurate palpation must be combined with radium knowledge and experience in order to give the patient the chance for life to which she is entitled. Hence anyone who attempts this work should have substantial training in both gynecology and radiology.

In the Washington University Medical School and Barnes Hospital, we have been

using radium and X-ray therapy systematically and fairly uniformly since 1921. Our cases have been analyzed and 5 year cures and other features reported from time to time.² The object of this paper is to call attention to certain late complications encountered in the 371 irradiation cases treated from July 1, 1921 to January 1, 1933. The disturbances under consideration are noticed one to several years after treatment, hence the series includes only cases treated prior to 1933.

These late complications are apparently due to slow vascular changes resulting in localized tissue devitalization. Also present are slow infiltration and necrosis with resulting contraction. Considering the intensive irradiation required for this deep seated cancer these lesions are rare in noticeable grades as evidenced by the small number in this series. This type of lesion was found in the rectum as a stricture, in the bladder as an indolent ulcer, and in the skin as a persisting and increasing subcutaneous infiltration leading occasionally (in one case) to extensive necrosis. The amount of radium employed was approximately 100 milligrams and it was screened with $\frac{1}{8}$ millimeter of silver and 1 millimeter of brass. In addition, the capsules were placed in soft rubber tubing and distance

²Presented before the Texas Association of Obstetricians and Gynecologists, San Antonio, Texas, September 30, 1931.

screening of the bladder and rectum was secured by firm packing adapted to the particular conditions present. In most of the cases of this series, the course of treatment was started with the radium implantation. The details of the X-ray treatments are given in each case showing subcutaneous infiltration

RECTAL STRICTURES

CASE 1. J. P. aged 44 years, in May 1933 received 4800 milligram hours of radium for a squamous cell carcinoma of cervix of clinical stage II. League of Nations International Classification. In this case radical abdominal operation was employed, the operation being carried out a few days after the finish of the radium dosage (which was given in two treatments with an interval of 4 weeks). Following the operation the patient received deep X-ray therapy.

Two years after treatment (August 1935, a rectal stricture was found. It was adjacent to the cervix area where the radium had been applied. It admitted the tip of the finger and was easily dilated, the walls being thin and without extensive induration. There was no indication of cancer in the rectum or elsewhere. In 1938 there was still slight narrowing but no symptoms from it. In June, 1939, there was no disturbance from the rectum or vicinity and no evidence of cancer. In February, 1931, the patient developed symptoms of brain tumor from which she died 4 months later. No evidence of cancer in pelvis. An autopsy was not obtained.

CASE 2. B. S. aged 46 years. In October 1930, patient received 4500 milligram hours of radium for squamous cell carcinoma of cervix of clinical stage III and also the usual deep X-ray therapy. In July 1932 there was definite rectal constriction in the cervical region. This was easily kept open so that there were no troublesome symptoms, but there was still some constriction at examination in June, 1934. There was no evidence of recurrence of the carcinoma. This patient had also a second degree X-ray infiltration of the abdominal wall (see under late X-ray effects).

CASE 3. S. L. aged 43 years. In September 1931, patient received 3000 milligram hours of radium for a squamous cell carcinoma of cervix of clinical stage III, followed by deep X-ray therapy. In a routine check-up examination in September 1933 a rectal stricture was found opposite the cervix. It was wide and admitted the finger easily for dilatation and had given no special trouble. In April, 1934 the rectal stricture was about the same. There was no evidence of recurrence of the cancer.

CASE 4. S. G. aged 61 years. In September 1932, patient received 4000 milligram hours of radium for squamous cell carcinoma of clinical stage III and the usual deep X-ray therapy. Check-up examination showed no evidence of recurrence of the cancer

but in the examination in August, 1933 a rectal stricture was found. This was adjacent to the cervix, and the walls were thick and firm. The opening was small and was dilated with some difficulty. In March, 1934, the stricture was causing no trouble. It is to be noted that this stricture gave trouble about a year after treatment, while those previously mentioned were not noticed until 2 years after treatment.

CASE 5. L. F., aged 45 years. In February 1932, patient received 3000 milligram hours of radium for squamous cell carcinoma of cervix of clinical stage III and also deep X-ray therapy. This case gives a clear indication of the etiology of these strictures. We have come to expect considerable rectal irritation in the effective irradiation treatment of carcinoma of the cervix, the rectal mucosa apparently being more susceptible to the acute effect than the bladder mucosa. Ordinarily the rectal irritation subsides after 2 or 3 weeks without further trouble. In some instances, however, the rectal irritation progresses to ulceration and infiltration with subsequent stricture formation.

In this case the rectal irritation persisted and after 3 months (in May 1932) there was definite ulceration. This gradually healed, but with evident beginning stricture from the scar tissue. This emphasizes the importance of investigation and treatment of any persisting rectal symptoms and also of rectal palpation in the check up examinations of these cancer patients. This patient had also a first degree X-ray infiltration of the skin of the abdominal wall (see under late X-ray effects).

BLADDER ULCERATION

CASE 1. B. H. aged 45 years. In June, 1925, received 3800 milligram hours of radium (in two treatments close together) for squamous cell carcinoma of cervix of clinical stage late II and also the regular deep X-ray therapy. Patient remained in good health for 3 years (until August, 1926) when she complained of bladder symptoms and the passing of bloody urine. Cystoscopic examination revealed a small ulcer in the bladder opposite the cervical region. This healed promptly under silver nitrate irrigations, and the bladder symptoms disappeared. There was no evidence of recurrence of the cancer. Subsequent check-up examinations showed no evidence of recurrence of the cancer and no bladder disturbance. In an examination in June 1930, the patient showed a marked hypertension, and in December she died of apoplexy. No autopsy was obtained.

CASE 2. E. P. aged 33. In September 1925, received 3000 milligram hours of radium for squamous cell carcinoma of cervix of clinical stage III. The patient received also deep X-ray therapy of which details will be given later as this is the patient with

sloughing of the skin mentioned under late X ray complications. In March 1928 this patient complained of bladder symptoms and on vaginal palpation there was a firm infiltration involving the bladder wall near the cervix. Cystoscopic examination showed just beyond the trigone an area of elevation varicosities submucous hemorrhage, and a small ulcer. It gave the impression of chronic inflammation rather than malignancy, and the subsequent course confirmed this diagnosis. This bladder disturbance cleared up under irrigations and instillations. The patient has been kept under observation, the last examination being in June 1934 and at no time has there been any evidence of the malignancy for which she received treatment in 1925.

CASE 3. R. H. aged 64 in June 1926 received 4000 milligram hours of radium for squamous cell carcinoma of cervix of clinical stage III and the usual deep X ray therapy. Patient remained well until January 1933 when she developed bladder distress and bloody urine. Cystoscopic examination showed an area of partial devitalization about 2 centimeters in diameter just above the level of the ureteral orifices. Surrounding the area were numerous dilated blood vessels radiating somewhat like the spokes of a wheel. Figure 1 (frontispiece) gives a very good representation of the cystoscopic appearance. The vessels bled easily when traumatized.

A small piece of tissue was removed from the area by Dr. J. R. Caulk, who had charge of the cystoscopic work in these cases. Microscopic investigation of the removed tissue showed chronic inflammation but no malignancy. Two fulguration treatments stopped the bleeding and the bladder irritability gradually lessened. In June, 1934 there had been no more bloody urine and the bladder symptoms were greatly improved.

CASE 4. A. S., aged 46 years, in August, 1929, received 3600 milligram hours of radium for adenocarcinoma of cervix of clinical stage III and the regular deep X ray therapy. The patient had also myoma of uterus and exophthalmic goiter and received medical treatment for the latter. The patient was in good health until July 1932 when she began to have bladder distress and passed bloody urine.

Cystoscopic examination revealed numerous dilated blood vessels in the portion of bladder opposite the cervix. Between the vessels, the bladder wall was pale and in the center was a grayish area. The entire field involved was about 3 by 4 centimeters, and it bled easily when touched. Scrapings removed through the cystoscope showed chronic inflammation but no malignancy. The bleeding was easily controlled by irrigations and instillations. Check up examinations in July and September 1933 showed absence of any further bleeding and not much bladder disturbance. At no time was there evidence of recurrence of the cancer for which treatment was given in 1929.

Of these 4 cases of late bladder complications the interval between irradiation treat-

ment and appearance of bladder trouble was 3 years 2½ years, 6 years and 3 years, respectively. The bladder symptoms developed rather suddenly and were soon followed by bloody urine. Cystoscopic examination showed a fairly uniform picture consisting of a devitalized area or ulcer with radiating dilated blood vessels (Fig. 1 frontispiece). The area bled easily when traumatized. Specimens removed through the cystoscope showed chronic inflammation without malignancy. In these particular cases the subsequent history showed the absence of accompanying malignancy, though such a non malignant lesion might occur in a case showing recurrent cancer activity either at that time or later. The lesion and resulting bladder symptoms yielded fairly well to irrigations and instillations fulguration to stop bleeding being required in only one case.

SLoughing OF SKIN

Pigmentation of the skin is of course to be expected over portals of entry for therapeutic roentgenization and is not counted of pathological significance. The late complication here referred to is a marked subcutaneous infiltration which caused thickening and irregularity of the skin and was later followed by sloughing.

CASE E. P. aged 33 years. In September 1925 received 3000 milligram hours of radium for squamous cell carcinoma of cervix of clinical stage III, and also deep X ray therapy. The X ray therapy was given in treatments on September 9 1925 November 4 1925 January 18 1926 March 23 1926 May 7 1926 July 15 1926 and November 26 1926. Each dose (given in two areas—one front and one back), milliamperes 30 time, 13 minutes kilovolts 200 filter 1 millimeter copper 1 millimeter aluminum portal 20 centimeters distance 50 centimeters.

Check up examinations from time to time showed the pelvis clear of evidence of recurrence of the cancer. As early as the latter part of 1926 it was noticed that there was an infiltration of the skin over an area of about 6 by 7 centimeters on the lower abdomen just above the symphysis pubis. Besides being highly pigmented, the skin was somewhat oedematous, with a deep firm infiltration. There was a smaller area presenting similar characteristics posteriorly over the sacrum. In October 1927 the subcutaneous infiltration had increased and definite telangiectasis was appearing in the areas. Figure 2 (frontispiece) gives a very good idea of the condition of the abdominal wall at this time. In March 1928

the patient developed an ulcer of the bladder which is reported as Case 2 under bladder ulceration. This yielded to treatment as previously mentioned. The abdominal wall infiltration showed increasing telangiectasis and serious local irritation. Figure 3 (frontispiece) shows the condition of the abdominal wall at this time.

The patient disappeared and did not return until October 1932. As the reason for not returning, she stated the skin of the lower abdomen sloughed away keeping her in bed for a period of 18 months. Apparently an area about the size of the hand in the involved region of the lower abdomen had necrosed. The necrosed skin had sloughed away to the subcutaneous tissue, leaving a large granulating surface. The patient was very stout with overhanging abdominal wall, and the granulating surfaces, being approximated, had healed together. At the visit in October 1932 the process of healing was only partly completed. There was still a small granulating area in the right side, and the healed area was tender. On her return, September 11, 1933, the abdomen was entirely healed. The line of scar tissue is shown in the photograph in Figure 4. In the right side of the scar there was an infiltrated area forming a small nodule. This was excised for microscopic investigation and showed chronic inflammation without malignancy. Over the scar area there was much infiltration and vascularization, but no sloughing. The photograph in Figure 5 is to show this area of discoloration. Naturally we have been watching the abdominal surface for malignant change, but so far none has appeared. At the last examination in June 1934, the patient was in good general health, and up and about her work without serious discomfort. At no time has there been any evidence of recurrence of the cancer for which she received treatment in 1925.

As to the etiology of this complication—why it appears in an occasional individual and not in others—the idiosyncrasies of the patient with the special reactions of her skin and subcutaneous tissues and blood and lymph must be taken into consideration. It is to be hoped that the study of this and allied conditions will develop some method of spotting those individuals with handicaps which limit their capacity to stand deep roentgenization.

In the course of check up examinations we have noted two lesser grades of what appears to be the same process. One case showed a very mild change in the skin and subcutaneous tissue.

This patient, aged 45, was given radium and deep X-ray therapy in February 1932. She developed a marked proctitis with some ulceration and later a rectal stricture, which is reported as Case 5 under

rectal strictures. The X-ray therapy consisted of 1030 r to lower abdomen on February 16, 1932, and 850 r to lower back on February 17, 1932. May 19, 1933, the patient complained of pain in the lower abdomen and vulva and thighs. Examination showed the abdomen markedly pigmented below the umbilicus with absence of pubic hair. No special vascularity was seen. There was some deep infiltration, causing thickening and irregularity of the skin. In June, 1934, the condition remained about the same.

Another case showed what may be designated as the second stage of the process, in which there was obvious vascular change in the form of telangiectasis.

This patient, aged 46 years, received radium and X-ray therapy in October 1930. She developed a mild rectal stricture, and is reported as Case 3 under rectal strictures. The X-ray therapy consisted of 900 r to lower abdomen on September 30, 1930, and 1000 r to lower back on October 1, 1930.

In the examination in June, 1932, it was noted that there was chronic infiltration of the abdominal wall with some superficial vascularity. By December 1932, the condition of the wall was definitely worse, the skin being raised in parallel ridges. In September 1933, the process showed no further progress, giving the impression that it had reached its maximum. June, 1934, the telangiectasis was more marked, pain in the abdominal wall was increasing, and the condition was becoming definitely worse.

GENERAL PLAN OF IRRADIATION TREATMENT

In order to improve the follow up in our cancer cases and better co-ordinate the work of the various services required in their treatment, we established some years ago a gynecological cancer clinic. This clinic is held every Tuesday afternoon and all cancer cases of the general gynecological clinic are referred to it. A special history is made in each case and a careful description of the growth recorded. The clinical classification of the cancer is made as far as conditions will permit, placing it in stage I, II, III, or IV of the League of Nations International Classification. A specimen is taken and sent to the laboratory for microscopic investigation and a bacterial culture also is taken from the growth as a control in clearing up the pyogenic infection which is usually present. Antiseptic douches are begun to be continued while the special treatment for the cancer is being carried out. The patient is immediately turned over to the

FIG. 1. Lat devitalization ulcer of bladder appearing 6 y. after irradiation treatment of carcinoma of cervix. The grayish appearance with numerous dilated blood vessels radiating toward the center is typical of this lat devitalization lesion. It is located opposite the cervix region, may appear from several years after the irradiation, and yields readily to treatment.

FIG. 2. Late subcutaneous infiltration of abdominal wall, appearing 2 years after irradiation treatment of carcinoma of cervix. Third degree, with deep extensive infiltration and marked widespread vascularization of the surface.

FIG. 3. The same abdomen as shown in Figure 2, but 3 months later. The devitalization had definitely progressed, and there was a small bluish area which appeared to be beginning necrosis.

Late Complications in Irradiation Treatment of Cancer of Cervix.
—Quinn J. Neuell and Harry S. Crossen.

Fig 4. Photograph of the same abdomen shown in Figure 3 (frontispiece) but 5 years later. An area the size of a hand had sloughed to the subcutaneous tissue. The granulating surfaces of the lax wall had fallen together and united. Microscopic examination of a section removed from the suspicious area on the right side showed no malignancy.

Fig 5. Same patient as in Figure 4. Back view to show the discoloration of the skin over the sacral area, where there was much infiltration and vascularization but no sloughing.

social worker and it should be emphasized that a good social worker is very important. She sees these ward patients in the clinic and hospital and, after dismissal from the hospital, sees that they return to the cancer clinic at the appointed time. She makes all appointments for X ray treatments with the Department of Radiology. The Department of Radiology has full charge of the deep X ray therapy, and works in close co-operation with the gynecologist. The gynecologist has full charge of the radium treatment and makes all radium implantations.

The systematic course of irradiation extends over a period of about 3 months. It is usually started with deep X ray therapy in order to secure some devitalizing effect on the outlying cancer cells before the stir up of the radium implantation in the center of the mass. This preliminary X ray therapy and course of local antiseptic treatment before the radium implantation is especially important where there is associated infection, as there usually is with ulceration or papillary formation. Two or 3 weeks after the preliminary roentgenization, the patient is hospitalized for the radium treatment.

After accurate implantation of the radium the bladder and rectum are pushed away by a

very firm packing in order to permit the maximum radium dosage which can be safely given with the conditions present in that pelvis. The packing is so firm that the patient can not urinate and on this account and also to keep the bladder empty and away from the radium, a retained catheter is used. The maximum dosage which can be given safely depends largely on how far away the bladder and rectum can be pushed by the packing. This depends on the amount of fixation of these structures by the carcinomatous infiltration and of course varies in each case. As a rule the infiltration is mainly into the lateral parametral tissues, with only late involvement of the bladder and rectal walls. At the time of the radium implantation, a careful examination under analgesia is made and a definite decision reached and recorded as to the clinical classification of the case. It is well also to make another bacterial culture at this time. For the radium treatment the patient ordinarily remains in the hospital about 5 days and after discharge returns to the clinic for check up examinations. About 8 weeks after the radium treatment the patient is given the second series of deep X ray.

This 3 months course of treatment comprises the regular course. Additional X ray or radium treatment is given only on special indication. After the 3 months course the patient returns for check up examination.

about every 2 months the first and second years every 3 months the third year every 4 months the fourth year every 6 months the fifth year and once a year after that. Of course if there is any local disturbance between times the patient is to come at once.

CONCLUSIONS

In the intensive irradiation treatment of 371 patients with carcinoma of the cervix most of them advanced we have encountered the following late complications:

Rectal stricture 5 cases mostly mild and all yielding satisfactorily to dilatation treatment.

Bladder ulceration 4 cases all responding to irrigations and instillations and only 1 requiring fulguration to stop bleeding.

Sloughing of the skin 1 case of extensive sloughing with subsequent healing. There was also 1 case of subcutaneous infiltration (first

degree) which seemed stationary and 1 case of subcutaneous infiltration with superficial vascular change (second degree) which was definitely progressive.

Of course some mild rectal strictures and lesser grades of subcutaneous infiltration may have escaped observation but the more serious lesions are not likely to be missed. We feel that we have been very fortunate to have accomplished so much in this disease, with so few serious complications. This applies both to the radium and the X-ray therapy. The radiologist Dr. Sherwood Moore, has succeeded in giving massive doses of X-ray which aided materially in curing patients and in giving temporary relief to others, with very few of the serious late effects. However we are always seeking improvements, and one of the problems of the day is the difficult task of diminishing still further the incidence of such complications.

THE CAUSE OF DEATH DUE TO LIVER AUTOLYSIS¹

EDWARD C. MASON M.D. PH.D. AND CARL A. NAU M.A. M.D. OKLAHOMA CITY OKLAHOMA
 From the Department of Physiology University of Oklahoma, School of Medicine

CONSIDERABLE confusion has developed in an attempt to explain the cause of death when liver tissue is found free within the abdomen. The observations presented by the various studies on this subject are often quite contradictory, however, the several authors state that one of the three following factors is the cause of death (1) a toxic substance generated in the autolyzing liver (4, 5, 6, 1), (2) the presence of bacilli resembling the *Bacillus welchii* (3) (3) anhydremia due to the loss of fluid into the abdominal cavity (7).

We have continued our studies in order to determine if the type of diet could in any way modify our previous results. While these studies were being conducted we have been making additional observations which we believe furnish a satisfactory explanation for the cause of death.

THE EFFECT OF HERBIVOROUS DIET

Rabbit 1 Female weight 8.25 pounds Nembutal anesthesia 1.6 cubic centimeters (1 grain per cubic centimeter) intraperitoneally supplemented with ether October 23 8.40 p.m. under aseptic precautions 16.5 grams of liver was removed from a second rabbit and placed high in the abdominal cavity. October 24 animal had quiet day. Water consumption in 24 hours was 500 cubic centimeters. October 25 8.30 a.m. animal was very active and alert. November 6 (14 days after operation) weight 8.25 pounds. The rabbit was killed and postmortem examination was made.

Rabbit 2 Female, weight 7.25 pounds. The procedure the same as for rabbit 1 was used. October 27 30 grams of liver including the gall bladder placed in the abdominal cavity. October 28 animal quiet but alert. October 29 animal was alert and active. November 6 10 days after operation, animal weighed 6.75 pounds. It was killed and a postmortem examination was made.

Rabbit 3 Male, weight 7.75 pounds. Same procedure as in previous experiments was used. November 4, 42 grams of liver was placed in the abdominal cavity. November 6 animal was alert, active and taking food and water. November 6 56 hours after operation, animal weighed 7.5 pounds. It was killed and postmortem examination was made.

The results of these experiments do not agree with the findings of Andrews and Hdrna (1) who state "The influence of diet was then studied by using herbivorous animals and the liver of 1 rabbit was planted into 5 other rabbits and exactly the same clinical picture of autolytic peritonitis was produced."

Dog 1 Female, weight 24 pounds. Preliminary preparation consisted in a high carbohydrate, low protein diet for 3 weeks. At 8.00 p.m. nembutal 3.4 cubic centimeters (1 grain per cubic centimeter) was given. At 8.45 p.m. this was supplemented with ether, and 30.5 grams of liver was removed and placed high in the abdominal cavity. At 10.00 p.m., the condition was good. At 7.45 a.m., the animal was dead, 10 hours after operation.

Dog 2 Female. High carbohydrate low protein diet was given for 5 weeks and 3 days. At 9.30 p.m. ether anesthesia was administered, and 46.75 grams of liver was sectioned and placed in the abdomen. At 10.00 p.m., the dog was in good condition. At 11.10 a.m. the animal was dead 13 hours, 40 minutes after operation.

These two dogs fed on a high carbohydrate diet showed no additional resistance, they lived only 10 hours and 13 hours 40 minutes respectively, following the operation. These are probably the most sudden deaths we have recorded.

THE EFFECT OF DOG LIVER IN RABBITS AND RABBIT LIVER IN DOGS

Confronted with the fact that rabbits survived the operation while dogs on a similar diet did not we next attempted to learn if the rabbits resistance was due to the increased resistance of their intact liver or due to the fact that the sectioned liver did not yield such toxic substances.

Rabbit 4 Weight 6.25 pounds. Nembutal and ether anesthesia was used. At 10.40 a.m. 3 grams of dog liver was removed while the animal was alive and placed in the abdomen of the rabbit. At 11.00 p.m. animal was alive but not in good condition. It was found dead the next morning.

Rabbit 5 Weight 7.75 pounds. Same anesthesia as for rabbit 4 was used. At 10.00 a.m. 21 grams of fresh dog liver was placed into the abdomen. At 5.15 p.m. breathing was labored and rabbit was

Fig. 1 Rabbit liver tissue undergoing aseptic autolysis

very listless. It was found dead the next morning.

Rabbit 6 Weight 8.25 pounds. The same anesthesia was used as in previous experiments. At 10:35 a.m. 30 grams of fresh dog liver was placed in the abdomen. At 5:15 p.m. the rabbit was alert and appeared well. It was found dead the next morning.

Rabbit 7 Weight 8.25 pounds. The same anesthesia as formerly was used. At 10:15 a.m., 18.25 grams of fresh dog liver was placed in the abdomen. At 1:15 the animal was sitting up and was alert. At 5:15 p.m. animal was apparently well. It was found dead the next morning.

Dog 5 Male Weight 33 pounds. Nembutal and ether anesthesia was used. At 7:30 p.m. 73 grams of liver was removed from a rabbit while it was alive and placed into the abdomen of the dog. At 8:45 a.m. the dog was standing. It drank much fluid during the day, the intake being approximately 1210 cubic centimeters above the output. At 7:00 a.m. (second day) the dog was found dead. Death occurred about 30 hours after operation. At 9:30 a.m. postmortem examination revealed the usual findings with 300 cubic centimeters of fluid in the abdominal cavity.

THE RELATIVE TOXICITY OF IMPLANTED CENTRAL AND PERIPHERAL LIVER TISSUE

Desiring to obtain additional support for our original observation in which we found that rabbits survived the operation we extended our series to include 3 more rabbits. However, in order to use fewer animals we removed the entire liver of 1 rabbit and divided it into three approximately equal portions. One piece was then placed into the abdomen of each of 3 animals with the following results.

Rabbit 8 Weight 8.25 pounds. At 10:30 a.m. 37.5 grams of liver was inserted. At 7:50 a.m. the next day the animal died.

Rabbit 9 Weight 6 pounds. The animal died the morning after 38 grams of liver had been inserted.

Rabbit 10 Weight 7.25 pounds. The animal died the morning after 41.5 grams of liver had been inserted.

Fig. 2 Rabbit liver tissue undergoing aseptic autolysis. Greater magnification than used in Figure 1.

These findings are contrary to our original observation and therefore agree with those reported by Andrews and Hrdina (1). It will also be noted that our technique in this series of rabbits was the same as that employed by Andrews and Hrdina, that is, introducing the entire liver of one animal into the abdomen of several other animals. Analysis of these results suggested to us that the only difference in the procedure used in the surviving animals and those that died, was the difference in the location from which the implanted liver was selected. In the former animals we introduced liver sectioned from the periphery while in the latter the sectioned liver included the central portion.

The following experiment illustrates the fact that implanted liver taken from the peripheral portion is less toxic than that taken from the central portion.

Rabbit 11 Weight 8.25 pounds. At 8:15 p.m., 15.9 grams of liver (peripheral portion) removed from a second rabbit and implanted. At 11:00, noon, the following day, rabbit was quite active and remained in good condition. It was killed 67 hours following operation and postmortem examination was made.

Rabbit 12 Weight 7.25 pounds. At 8:30 p.m., 15.9 grams of liver (central portion) was removed

Fig. 3a. The host's liver (rabbit) accompanying the presence of aseptic autolysis.

Fig. 3b. The host's liver (rabbit) accompanying aseptic autolysis.

from a second rabbit and implanted. At 8:15 a.m. the following day condition was good. At 10:30 a.m. animal died suddenly. Condition appeared good 10 minutes before death. Postmortem examination was made.

A STUDY OF THE HISTOLOGICAL AND BACTERIOLOGICAL CHANGES

The animals which survived the operation, that is those which received peripheral liver tissue were subsequently killed and an autopsy performed. The examination revealed a postmortem condition quite different from that which we have previously found (4) in the non-surviving animals. The implanted liver is firmly adherent to a loop of bowel. It is creamy-green in color, contains no gas and no odor. Occasionally, there is present only a small amount of free fluid in the peritoneal cavity. The sectioned liver shows a marked loss of weight ranging from 24 to 54 per cent in 10 days and 14 days respectively. This loss of weight is the result of phagocytic action and is well illustrated in the microscopic sections.

Figure 1 is an enlarged photograph of a paraffin section of liver tissue undergoing aseptic autolysis. It will be noted that the invading phagocytic cells are arranged in a dense formation producing a definite line below the liver capsule.

Figure 2 is a photomicrograph of the section in Figure 1 and shows the process more in detail.

While the autolysis illustrated is taking place in the implanted liver, the host's organs are also definitely damaged. Accompanying such damage the animals showed definite toxic symptoms.

Sections of the host's liver and kidney are presented in Figures 3a and b and Figure 4. Dr. L. A. Turley of the Department of Pathology gives the following description of the liver and kidney. This description is confined to tissue obtained by killing the rabbits ten days postoperative.

Liver "Cords of central and middle zones of the lobules show rarefaction so marked that the nuclei of the cells appear to be held in place by a lace like web. The cells of the peripheral zones have a fine, foamy appearance. The tissues of the portal canals are infiltrated with lymphocytes, endothelial cells and an occasional polymorphonuclear leucocyte. This infiltration is most marked around the bile ducts. This liver is the victim of what appears to be a rather acute and marked fatty degeneration plus a septic cholangitis."

Kidney "The lesions in the kidney vary with the different fields. In some fields the capillaries of the tufts and tubules are en-

Fig. 1. Rabbit liver tissue undergoing aseptic autolysis

very listless. It was found dead the next morning.

Rabbit 6 Weight 8.25 pounds. The same anesthesia was used as in previous experiments. At 10:25 a.m. 20 grams of fresh dog liver was placed in the abdomen. At 5:15 p.m. the rabbit was alert and appeared well. It was found dead the next morning.

Rabbit 7 Weight 8.25 pounds. The same anesthesia as formerly was used. At 10:15 a.m. 18.25 grams of fresh dog liver was placed in the abdomen. At 1:15 the animal was sitting up and was alert. At 5:15 p.m. animal was apparently well. It was found dead the next morning.

Dog 3 Male Weight 33 pounds. Nembutal and ether anesthesia was used. At 7:30 p.m. 73 grams of liver was removed from a rabbit while it was alive and placed into the abdomen of the dog. At 8:45 a.m. the dog was standing. It drank much fluid during the day, the intake being approximately 120 cubic centimeters above the output. At 7:00 a.m. (second day) the dog was found dead. Death occurred about 30 hours after operation. At 9:30 a.m. postmortem examination revealed the usual findings with 300 cubic centimeters of fluid in the abdominal cavity.

THE RELATIVE TOXICITY OF IMPLANTED CENTRAL AND PERIPHERAL LIVER TISSUE

Desiring to obtain additional support for our original observation in which we found that rabbits survived the operation we extended our series to include 3 more rabbits. However in order to use fewer animals we removed the entire liver of 1 rabbit and divided it into three approximately equal portions. One piece was then placed into the abdomen of each of 3 animals with the following results.

Rabbit 8 Weight 8.25 pounds. At 10:30 a.m. 37.5 grams of liver was inserted. At 7:50 a.m. the next day the animal died.

Rabbit 9 Weight 6 pounds. The animal died the morning after 38 grams of liver had been inserted.

Rabbit 10 Weight 7.25 pounds. The animal died the morning after 41.5 grams of liver had been inserted.

Fig. 2. Rabbit liver tissue undergoing aseptic autolysis. Greater magnification than used in Figure 1.

These findings are contrary to our original observation and therefore agree with those reported by Andrews and Hrdina (1). It will also be noted that our technique in this series of rabbits was the same as that employed by Andrews and Hrdina, that is, introducing the entire liver of one animal into the abdomen of several other animals. Analysis of these results suggested to us that the only difference in the procedure used in the surviving animals and those that died was the difference in the location from which the implanted liver was selected. In the former animals we introduced liver sectioned from the periphery while in the latter the sectioned liver included the central portion.

The following experiment illustrates the fact that implanted liver taken from the peripheral portion is less toxic than that taken from the central portion.

Rabbit 11 Weight 8.25 pounds. At 8:15 p.m. 150 grams of liver (peripheral portion) removed from a second rabbit and implanted. At 12:00 noon, the following day rabbit was quite active and remained in good condition. It was killed 67 hours following operation and postmortem examination was made.

Rabbit 12 Weight 7.25 pounds. At 8:30 p.m. 150 grams of liver (central portion) was removed

Fig. 6 Organism obtained from central portion of rabbit liver

Fig. 7 Impression smear of the liver from incubated rabbit 13

into each of rabbits 13 and 14. After 5 minutes rabbit 13 was killed and placed in an incubator for 22 hours. Autopsy at this time showed the following. The liver was soft and friable with a consistency that of soft cottage cheese. All the tissues were crepitant. The striated muscle was riddled and the odor was very foul. Impression smears were made and stained by the Gram's method which showed enormous numbers of positive rods identical with those found in the autolyzed liver of rabbit 12.

Rabbit 14 Was permitted to live and showed no ill effects from the injection.

Figure 6 is a photomicrograph of the organism which was obtained from the culture of the central portion of liver, part of which was implanted in rabbit 12. The peripheral portion of the same liver and that which was introduced into rabbit 11 on culture showed no anaerobic organisms.

Figure 7 was obtained as an impression smear from rabbit 13. The source of the organism was the same as that reported in Figure 6.

DEDUCTIONS

Sectioned liver tissue undergoing aseptic autolysis within the abdomen is accompanied by definite damage to the host. This is evidenced by changes in liver and kidney of host and also by toxic symptoms manifested.

In all of our previous reports on this subject, the experimental data were obtained from dogs. Therefore when the first 3 rabbits of this series survived the operation we were of

the opinion that the survival was due to the type of diet selected by the rabbit. This conclusion also agreed with the observation of Salzmann who found that rats either survived the operation or died depending entirely upon the type of diet fed the animals.

Continuing our experiments we have been forced to conclude that all the surviving animals received implanted liver tissue sectioned from the periphery of the liver. Such tissue proved to be free of the anaerobic bacillus. We further observed that the implanted liver tissue sectioned from the central portion caused death and also gave a positive culture for the organism. It has been observed by Andrews et al. (1) and also by Dvorak that this organism may be injected in large amounts into the peritoneal cavity without causing the death of the animal. We have injected the organism intravenously and found it affected the animals but little if at all. However if shortly after such an injection we killed and incubated the animal we subsequently found the tissues completely riddled by the organism, the liver being destroyed.

The sequence of events which leads to the death of the animals appears to be as follows. The bacteria remain in a latent state until stimulated to activity by the asphyxiation of the liver tissue. The activity of the bacteria then accelerates the production of toxic prod-

ucts and these in turn cause death by producing a chemical reaction. The picture is not that which we usually consider as a generalized peritonitis but the bacteria confine their activity locally to the selected substrate. Also the rapidity with which death follows the operation after 10 to 15 hours is not in keeping with the usual picture of peritonitis. The damage to the tissues of the host shown in the microscopic sections, with and without the presence of bacteria, rather suggests that the process which produces death is not necessarily a difference in kind but rather a difference in degree, the action of the bacteria only accelerating the liberation of toxins from the liver tissue. Trusler and Reeves have demonstrated the fact that the organism does not produce exotoxins and it has also been shown that the organism may be cultured within the abdomen, substrates other than adult liver tissue being used without causing death (3).

CONCLUSIONS

1. Additional evidence is submitted to support the contention that the absorption of dead and autolyzed tissue is associated with toxic symptoms on the part of the host.

2. Death is not due to a generalized peritonitis but rather to the absorption of toxic products generated from the liver tissue deprived of its circulation.

3. The anaerobic bacillus found at the time of death may be injected intraperitoneally and intravenously without causing any harmful results.

We wish to express our appreciation for the assistance given us by Miss Ida Lucille Brown of the Department of Bacteriology.

THE HISTOLOGY OF THE BILIARY DUCTS AND ITS CORRELATION WITH THE SYMPTOMATOLOGY OF COMMON DUCT STONE¹

IAN G MACDONALD M.D. C.M., CORNWALL, NEW YORK

STANDARD works of reference in medicine and surgery enumerate a remarkably uniform list of symptoms said to be caused by the presence of calculi in the extrahepatic biliary passages. In the past several years, the "asymptomatic common duct stone" has been the theme of several writers (3-6), but nevertheless the gathered opinions of members from several surgical staffs gave the impression that biliary colic is the chief signpost to a diagnosis of calculus in the common duct. In direct variance with this is a statement by Professor D. P. D. Wilkie of Edinburgh that common duct stone never gives rise to colic since that section of the biliary tract exhibits in its wall no muscular tissue, and is therefore non-contractile non-peristaltic. Attacks of biliary colic, Wilkie stated, are produced only by the passage of a stone along the cystic duct with its regular layers of musculature. This assertion seemed sufficiently novel to merit investigation, and if proved would obviously be of great diagnostic importance. The subject has been pursued along three lines:

1. Review of recent literature.
2. Study of the detailed histology of the bile ducts.
3. Analysis of case histories of patients proved to have had choledocholithiasis over a 5 year period at the Los Angeles County General Hospital and the Toronto General Hospital.

It will be shown that the correlation of anatomical findings with symptoms in these cases, with due reference to the duct histology outlined below, disprove practically all the commonly accepted explanations of pain production in biliary colic.

1. Much of the recent literature on the subject has been concerned with the absence of the classical signs and symptoms in many cases and the wide variance possible in the clinical picture. In 1877, Charcot first described the intermittent fever in common duct

obstruction which has since been associated with his name. Kehr in 1900 remarked that jaundice may be absent in common duct stone, and in Jordan's series of 106 operations for this condition 10.6 per cent of the patients were without jaundice. Oertel described a case in which complete common duct obstruction by stone had been compensated for by saccular dilatations of the ducts to such an extent that the patient died without jaundice. Mann's experiments verified this possibility in animals where dilatation of the ducts delayed the onset of jaundice. Clute reported that 31 per cent of his operative cases with common duct stone showed no jaundice. He recommended more frequent choledochotomy when operating for calculous cholecystic disease having found stones in the common duct in 18 per cent of his cases in a 3 year period due to this procedure. He remarked that a slight elevation of blood bilirubin often means common duct stone. A further series of cases reported by Klingenstein showed 6 per cent without jaundice and a slightly smaller percentage without colic.

The theories that have been advanced to account for causation of biliary colic are many and varied. Such are concerned with impaction of a calculus in the ampulla of Vater, distention of the ducts and the size and shape of the obstructing stone. The cases to be quoted below will suggest the futility of such explanations. Rolleston and McNee are authorities for the statement that severe biliary colic may be present in the absence of any calculi, being due to cholecystitis with inflammatory reaction in the sensitive sub-peritoneal tissues. Most commonly accepted is the view that colic is due to spasm of the ducts by their constituent muscular layers. With this in mind the investigation of the histology of the bile ducts was undertaken.

2. An amazing variance of ideas as to the normal histology of the bile ducts was encountered in the various standard works, old

Fig. Low power field from an area in a longitudinal section of the common bile duct, 2 millimeters distal to the sphincter of Oddi. Shows scattered muscle fibers, usually lying unidirectionally among fibrous and elastic tissue. At the lower edge are seen a few organized muscular strands tailing off from the sphincteric muscle. Phosphotungstic acid stain.

and recent. For example a large volume of *Special Cytology* published in 1928 (10) states that in the cystic duct exist three-directional smooth muscle fibers while in common and hepatic ducts only very small amounts are present and without definite layers. Max imow emphasizes the fact that only the common duct shows bundles of smooth muscle running in oblique and longitudinal directions, forming an incomplete layer around the duct. Burden observed that the hepatic, cystic, and common bile ducts are identical in structure there being bundles of unstripped muscle lying in the outer layer of areolar tissue together with blood vessels and lymphatics. He claimed that these muscle bundles were well developed and formed isolated longitudinal and circular layers thus producing a loose network rather than a compact layer. Rolleston and McNece make the bald statement that the bile ducts are without muscular tissue at any point but quote no proof of such statement. In spite of the fact that nearly all possible combinations seemed to have been exhausted by these various authorities, it was proposed to prove, if possible which of the statements here quoted was correct.

Microscopic sections were first made from the various parts of the bile duct—hepatic, cystic, and common. Three stains were employed: hematoxylin and eosin, phosphotungstic acid stain for muscle, and Weigert's for elastic tissue. As no muscular coats could be found in the bile ducts in the material examined from the first few autopsies, a more systematic method was followed.

The gall bladder and the cystic and common ducts down to the entrance of the latter into the duodenum and including a section of the duodenal wall were removed from cadavers showing no gross evidence of biliary tract infection. After being washed in water the preparation was injected through the ampulla of Vater with Zenker's solution until the ducts were moderately distended. When sufficiently fixed, sections were taken at regular levels, as follows:

- A Through sphincter of Oddi and along the terminal portion of the common duct
- B From proximal portion of common duct
- C From distal end of cystic duct
- D From proximal portion of cystic duct
- E Through the junction of cystic duct with the neck of the gall bladder

These sections were then stained with phosphotungstic acid which after study of numerous sections, was determined to be the best stain for the detection of muscle tissue. In all, 84 sections, some transverse but most of them longitudinal were prepared from the material obtained from 14 autopsies.

A study of these sections shows that the muscular coats, as such cease very abruptly at the neck of the gall bladder sometimes with a sphincter like structure at the origin of the cystic duct. The remainder of the biliary ducts—common, cystic, and hepatic, are merely fibro-elastic tubes, lined with a high columnar mucosa covered by a serosal layer with the usual subserosal areolar tissue. Only small isolated fibers of unstripped muscle are present sometimes indistinguishable from connective tissue cells. In many sections, a search of several high power fields is necessary to demonstrate even isolated muscle cells. A striking point in the study of many of these ducts is the presence of comparatively large glands in the duct walls, as described by Burden. It is a

Fig. 2 High power view of a field from Figure 1. Individual muscle fibers stand out in contrast to connective tissue.

Fig. 3 High power view of an area several low power fields distal to that in Figure 1. Note marked decrease in number of muscle fibers. Phosphotungstic acid stain.

real possibility that these glands offer lodging to organisms metastatic from other foci of infection and subsequently become responsible for low grade cholangitis. Nerve fibers are present in great abundance, usually distributed in the outer part of the wall.

3 The clinical review was confined to those cases definitely proved to have had calculi in the common duct. This reduced the number of cases in the 5 year period to 16 at the Toronto General Hospital (1926-31) and 8 at the Los Angeles County General Hospital (1927-32) in which stone had actually been removed from the common duct at operation or autopsy. When contrasted with the figures from other surgical clinics (Mayo Clinic 106 in 10 years, Mayo-Robson 380 in 10 years) this seems to indicate an extraordinarily low incidence of calculous cholecystic disease among hospital populations of over 30,000 (T.G.H.) and 90,000 (L.A.C.G.H.). This variation is due in part of course to the greater number of elective cases in other clinics.

The histories were examined as to 6 cardinal points (1) chronic indigestion (i.e. painful digestion) flatulence and so called bilious attacks with headaches as elicited in the past history, (2) dull pain in upper abdomen with radiation posteriorly (3) well defined biliary colic, (4) presence of jaundice, (5) chills, (6) fever. The relative frequency of

these findings for the two series of cases is presented in Tables I and II. In Table III is shown the percentage incidence of these signs and symptoms in the combined series.

Certain points are of interest even in this small series. Jaundice is the one near constant sign, yet one woman with a 3 year history and as many calculi in the common duct failed to show an icteroid tinge at any time although the icteric index was 13.7. Next in order is a high percentage with history of digestive upset or chronic upper abdominal pain or both over a period of years or at least months. *There was frequently acute exacerbation of such symptoms when the calculi presumably entered the biliary ducts* as shown by 81 per cent of the quoted cases. Much of this is due of course, to activation of chronic cholecystic disease but a perusal of these clinical histories leads one to believe that any individual who suffers in mid or late life a sudden up-trend in severity of previous cholecystic symptoms is an eligible candidate for the diagnosis of common duct stone. If this be associated with icterus and its accompanying manifestations or failing that an elevated blood bilirubin or with a dull radiating upper abdominal pain or with chills or fever the diagnosis becomes more than probable.

Fig. 4. Low power view of an area from the mid portion of the common bile duct. Virtual absence of muscle fibers. Large groups of hyperplastic glands in duct wall, some of which are cystic and dilated. Hematoxylin-eosin stain.

Fig. 5. Low power photomicrograph of an area from the mid portion of a cystic duct. There is complete absence of muscle fibers. Phosphotungstic acid stain.

Most unusual in this series is the extraordinarily low incidence of biliary colic. With the appearance of colic the difficulties of diagnosis are largely erased, but 56 per cent of these cases failed to present such conclusive evidence of common duct stone. In none of the 8 autopsy cases in which the pathologist was the final arbiter was the symptom of colic found in the medical history. This is certain indication of the reluctance with which a diagnosis of biliary duct calculus is surveyed without the *sine qua non* of colic.

Chills were a feature in 7 instances (26 per cent) and fever in 8 (29 per cent).

It should be mentioned that the dull upper abdominal pain complained of by some of these patients is by no means confined to the right upper quadrant. At least 4 (14 per cent) reported left upper quadrant pain and 3 epigastric pain. Two of the former patients had their radiation of pain to the left scapula.

Only 1 of the 27 cases presented all of the 6 cardinal features herein tabulated and a second 5. Ten or 37 per cent had 4 out of the 6 signs or symptoms, and 6 (22 per cent) only 3. Seven others had only jaundice and one other point, while 1 case presented only jaundice. In the aged, common duct stone, like acute appendicitis, seems remarkable for the lack of clinical evidence produced. Especially is this true of the colic symptom only patient in this series over 60 presenting this evidence.

Clute's advice regarding more frequent opening of the common duct during operative

procedures for cholelithiasis seems to be borne out in this series. Nine of the quoted cases had had previous cholecystectomies or cholecystotomies and several operative reports stated the bile ducts to be without exterior evidence of calculi. In experienced hands the mortality cannot be appreciably raised by the additional technique and time involved. There is certainly adequate compensation, even if convalescence is lengthened by duct drainage in the knowledge of a certain result. The formation of calculi in the intrahepatic ducts, as described by Judd and Burden is of great rarity.

Certain cases of this series merit special remark inasmuch as they illustrate the futility of attempting any reasonable explanation of pain production.

M. C. female, 40 years old, suffering severe colic, was found at operation to have the largest solitary stone in the series, 3 by 2.5 centimeters, in the common duct. It has been said that small stones produce most severe colic. In this instance, at least, a large stone produced severe colic.

J. F., aged 57 years, had had a cholecystectomy in 1923 and was admitted in 1928 with jaundice, fever, and chills. He was without pain or colic, and the autopsy showed a calculus of bean size impacted in the ampulla of Vater and behind it several smaller stones. The ducts were distended to several times normal diameter throughout. In brief, this individual had failed to develop colic or pain in spite of impaction of a stone in the ampulla, the presence of several small stones, and distention of the ducts—all of which conditions have been named at one time or another as causative of colic.

TABLE I—PROVED COMMON DUCT STONE

Key C I—Chronic indigestion, flatulence etc.
Radiation—Dull pain with radiation

J E was a man of 70 years who had suffered from dull epigastric pain for 10 years, but never from colic. In hospital he had a moderate increase of the pain with intermittent chills, fever and jaundice. Autopsy showed a marble sized stone occluding the ampulla of Vater with several others in the duct. In the liver were multiple abscesses. Again no colic in spite of multiple stones and occlusion.

M D, a woman 70 years of age presented increasing jaundice for 5 months. After admission to hospital her empyemic gall bladder was drained. Autopsy proved the common duct to contain 13 stones of various size. All the hepatic ducts were dilated. She had never suffered even dull pain, nausea, vomiting, and headaches were the only symptoms. Here multiple stones and dilatation of even intrahepatic ducts failed to produce pain.

F C was a man of 70 years, whom autopsy showed to have a carcinoma of the gall bladder with complete occlusion of the cystic duct by carcinomatous invasion. He died with a deep jaundice of 5 months standing which was found at autopsy to be due to stone obstructing the common duct itself quite patent, and with the remainder of the biliary tree free from carcinomatous invasion. This stone must therefore have been present for many weeks in the common duct (i.e. before the cystic duct became occluded by carcinoma) and was probably responsible for the marked jaundice. His only pain had been epigastric and of very moderate severity generally following meals. Thus, in spite of a calculus obstructing the common duct for many weeks—probably 5 months—this individual had never exhibited anything approaching a colic like pain.

Illustrating the necessity of common duct exploration in doubtful instances is the case of W F R a 64 year old male.

A. single stone	16	
Chronic indigestion, flatulence etc.	12	6
Dull pain with radiation	12	43
Biliary colic		44
Jaundice	3	93
Chills	1	26
Fever	1	20

Ten years before the last admission a cholecystectomy had been performed and this was followed by jaundice. During the following years he suffered from recurring indigestion and occasional dull epigastric pain. Before admission he developed a constant dull epigastric pain and pain in the right upper quadrant without radiation followed by a gradually developing jaundice. In hospital, a pre-operative diagnosis of catarrhal jaundice or adhesions was made and the occasional chills he complained of laid to hysteria. The jaundice cleared, the abdomen was opened, and gastro-enterostomy was done because of dense distorting adhesions about the pylorus. The biliary ducts were not explored. After a postoperative death an obstructing calculus was found at autopsy in the common bile duct.

The same point is illustrated by another case.

E. M., a 53 year old woman who 3 years before admission had been operated upon for empyema of the gall bladder. At that time a number of stones were

removed from the gall bladder and the gall bladder drained. She continued to have chronic right upper quadrant pain and flatulence for the 3 years, but no colic at any time. Eventually the common duct was explored and found to contain 3 large stones, and the duct itself was much thickened and dilated.

I. W. a male aged 70 years, illustrates the case with atypical distribution of pain. Having had a cholecystectomy 13 years previously his chief complaint on admission was left upper quadrant pain radiating to the left scapula. As he presented a marked jaundice and had constant chills and fever the common duct was explored and a solitary stone 3½ centimeter in diameter removed.

SUMMARY

1 Material has been examined to show that the biliary ducts possess throughout only small isolated fibers of muscle irregularly scattered. The bile ducts are fibro-elastic tubes, richly supplied with nerve fibers, lined by tall columnar epithelium and frequently featured by the presence of large subepithelial glands lying in the membrana propria singly and in groups.

2 Biliary colic is not caused by muscular spasm according to these histological findings. Several quoted cases go to show that most of the other theories usually advanced as etiological factors of pain are probably false.

3 Colic is by no means a constant symptom of calculi in the bile passages, as shown

by an absence of that symptom in 56 per cent of 27 cases presented.

4 The most frequent symptom of common duct stone is an exacerbation of previous indigestion flatulence or dull upper abdominal pain with or without radiation. The one near constant finding is jaundice.

5 A survey of this series impresses one with the need of more frequent exploration of the common duct as a combined procedure with cholecystectomy for cholelithiasis.

THE BLEEDING TENDENCY IN JAUNDICE¹

A. C. IVY M.D. PH.D. P. F. SHAPIRO M.D. AND P. MELNICK M.D. CHICAGO, ILLINOIS

From the Departments of Physiology and Surgery of Northwestern University Medical School and the Departments of Surgery and Pathology of the Cook County Hospital

THE surgical and medical risks of infections and other pathological processes in and about the liver are seriously augmented by the possibility of hepatic insufficiency. One of the most striking surgical features associated with these cases of liver damage is their tendency to bleed. According to the results obtained in several clinics 50 per cent of all postoperative deaths in patients with jaundice or liver insufficiency are a result of hemorrhage (8, 25, 26, 36). The following study was undertaken chiefly in an effort to reduce these operative risks.

DETERMINATION OF BLEEDING TENDENCY

The first objective was to devise a reliable clinical method that would disclose the latent hemorrhagic tendency in jaundiced patients. The great variability of bleeding tendency in jaundice is well known. Jaundiced patients with a normal Duke's bleeding time, normal coagulation time and normal blood coagulating factors will frequently bleed abnormally and patients with abnormal findings will frequently not bleed. Many clinical and laboratory methods have been recommended to determine the existence of a bleeding tendency but none of them so far has been an accurate guide. As Colbeck has stated there is no definite method as yet for the evaluation of the bleeding tendency in jaundice.

1. *Blood coagulation factors.* *In vitro* studies of the various blood coagulation factors in jaundice have been extensive. Analysis of the literature forces the conclusion that although there are variations in these factors these variations cannot be correlated reliably with the bleeding tendency. Changes in blood calcium, fibrinogen, platelets, prothrombin, antithrombin, sedimentation rate, etc. are observed just as frequently without as with a hemorrhagic diathesis in jaundice.

a. *Calcium.* There is undoubtedly a disturbed calcium metabolism in jaundice such as altered calcium balance, osteoporosis, etc.

As one of us (A. C. I. 14) has already pointed out, the literature does not agree on the relation between this disturbance of calcium and the hemorrhagic diathesis found in some cases. Blood calcium levels both fixed and diffusible are unchanged or only slightly changed in jaundice. The general weight of experimental evidence seems to uphold the view that although a functional deficiency of calcium exists, it has no relation to the bleeding tendency (Linton, 22; Snell and Greene, Gunther and Greenberg, Ivy, Wangensteen, Colbeck).

It is true that in jaundice intravenous calcium improves coagulation *in vitro* but the mechanism by which it does so is not clear. Furthermore, extravascular clotting has little relation to bleeding tendency. Following the lead of Mayo-Robson, Wright and Paramore, Lee and Vincent, Walters (34), Whipple, Judd and others, the pre-operative administration of calcium is widely used (Cantarow, McKnight, Webb, Brennan, Hanlon, Sistrunk and others). But failures are frequent. As Wangensteen and also Colbeck have summed up, intravenous calcium has not solved the problem of hemorrhage in jaundice.

Blood calcium determinations therefore are of no value in determining the bleeding tendency. The problem of diffusible calcium presented itself however and was studied in many of our cases. The results will be set forth in a separate communication.

b. *Other blood coagulation factors.* Bancroft, Kugelmass and Stanley Brown in a study of 200 surgical cases concluded that no one factor can be isolated as a cause of bleeding or clotting. They devised a "clotting index" calculated from a composite of the determinations of the prothrombin content, fibrinogen content, platelet count, degree of platelet lysis and antithrombin. In later studies they dropped the platelet count and lysis studies, because these could not be correlated with clinical bleeding. Another inter-

SURGERY GYNECOLOGY AND OBSTETRICS

esting conclusion was that the clotting tendency can be determined reliably after operation but not before, because when a bleeding tendency exists, the ether damage to the liver and operative shock make it manifest the liver and operative shock make it manifest.

For clinical use such a clotting index is entirely too elaborate (Mills, and Clute and Veal). But of greater importance it is probably inaccurate. The attempt to study the bleeding tendency by splitting it into many factors is misleading. One factor after another is heralded as the important one only to be dropped when found to be clinically unreliable. For in any given case one factor may compensate for another both in the calculation and clinically. In different bleeding conditions, different factors are involved. Furthermore, when all factors are normal the patient may still bleed because he may be on the threshold of bleeding and ether acidosis, operative shock etc may push him over this threshold. It seems as if the only way at present to determine a bleeding tendency is to see if the patient bleeds. Yet such a posteriori determinations would be of no value in preparing patients for operation.

With particular reference to jaundice the same conclusions apply. Lewisohn found a decrease in prothrombin and fibrinogen and an increase in antiprothrombin associated with increased risk of hemorrhage. Murakami and Yamaguchi found a decrease in fibrin ferment in jaundice. Johnson concluded that in experimental obstructive jaundice clotting was delayed because the quantity and quality of the fibrin seems deficient. But Linton found that in obstructive jaundice there is no deficiency in the blood fibrin in fact a distinct increase. Moss also found a distinct obstructive jaundice. Mann and Bollman found in plasma fibrinogen in experimental obstructive jaundice. Mann and Bollman found after removal of the liver that prothrombin did not change, antithrombin sometimes increased and sometimes decreased and fibrinogen remained normal for a time but after depletion did not regenerate. The sedimentation rate has also been suggested as a guide to the bleeding tendency in jaundice. Linton (21) considers it to be an accurate guide. Clute and Veal however consider it suggestive and helpful but not absolute.

As with calcium after much study determinations of other blood clotting factors were discarded in the present study as not furnishing a reliable guide.

2. Coagulation time. Determination of coagulation time is today a most widely used procedure. Yet it seems to have relatively little value. In many hundreds of cases studied by many authors (Kleinert, Hunt, Harter, Feinberg, Bland and Stanley Brown, Kugelmass, Bancroft and Stanley Brown, and others) the general conclusions are that prolonged clotting time seems to bear no relation to clinical dyscrasias and when normal in severe blood dyscrasias and bleeding occurs. The only condition in which a prolonged coagulation time is diagnostic is hemophilia. The multiplicity of methods devised for the determination of clotting time points to the difficulty in their evaluation. No less than 33 different methods (probably more) are known (Solis-Cohen). Moreover the numerous factors affecting the clotting time of shed blood such as contact with air, glass, and dirt, size and shape of drop amount of blood, mechanical disturbance and point of evaporation, temperature, dilution, meteorological factors, age, hemoglobin, food, fluid, contact with tissues, skin and lymph, pressure, character of the wound, etc. make the interpretation very difficult. In an exhaustive study of these points Solis-Cohen has analyzed all these points carefully. In spite of the unreliability of the method, it was decided in the present study to investigate the coagulation time. The methods of Bogg, Biffa, Lee and White and Howell were used. Those of Bogg and Biffa were first done on 115 normal individuals to get a standard. Up to 6 minutes was found normal with the Bogg's method (average range of 3 to 5 minutes) and up to 9 minutes for the Biffa method. In 60 cases of jaundice and in 25 miscellaneous pathological cases, the coagulation time was invariably found to be normal. Lee and White's method was done on 32 cases, and Howell's method on 30 cases. These were all normal.

In only 1 jaundice case was the Bogg's method above normal, 13 minutes. This patient

was operated upon and died, but of cholemia, not of hemorrhage. This would seem to indicate that the prolonged coagulation time in jaundice is not so much an index of bleeding tendency as of liver damage. Walters (35) agrees in this view.

Coagulation time, then, was also discarded along with calcium and other determinations as not being an accurate guide.

3 *Bleeding time* In bleeding conditions the simple fact is that the patient bleeds. The problem is how to demonstrate beforehand that he is going to bleed. Duke's bleeding time is used universally. To a large extent in jaundice it has been disappointing. Here it is of little more value than the coagulation time. True in severe anemia, febrile states, acute leucemias and in pronounced hemorrhagic diatheses in general it is prolonged, and is the single most reliable method of predicting a bleeding tendency. But a latent bleeding tendency, such as is found in many cases of jaundice, is not revealed by the ordinary puncture of the skin. Thus, it was felt that some way should be found to make a patient with a hypothetical latent bleeding tendency in jaundice bleed excessively from an ordinary skin puncture, and thus possibly make it manifest.

A factor which has received little attention in bleeding studies is the state of "tonicity" of the capillaries. In small vessels it is the retraction of their walls to a large extent which stops bleeding. No other factor can explain the fact that the normal bleeding time of 30 to 180 seconds (Duke) is much less than the normal coagulation time. Von Bermuth and Magnus have demonstrated this clearly, by actual observations of the capillaries with the capillary microscope. Magnus has shown that the normal capillary when cut, will contract force out its content of blood and then disappear completely from view because of its contraction. In a case of hemophilia, von Bermuth found that the capillaries did not contract after being cut but remained patent and continued to bleed. In a case of Werlhof's disease, however, the capillaries reacted in the normal manner. This field offers fascinating possibilities for study and should be investigated further.

It was felt that if the factor of capillary tonus could be eliminated and the capillaries kept wide open, the situation would be simplified and a latent bleeding tendency revealed if present. Such a situation is comparable clinically when ether, shock, operative trauma etc. results in capillary paresis and bleeding.

The skin of the forearm near the elbow over the pronator muscles was selected as being uniformly thin without the disturbing factor of differences in hornification present on the finger tips. Ordinary Duke's punctures (with mechanical stylet set a uniform depth of about 2.5 millimeters for all cases) gave the usual bleeding time as 30 seconds to 3 minutes. Heat was then applied and another puncture done. No constant change was noted. Cold was then used; no dependable difference could be noted. Histamine (which does not alter blood coagulability, Best and McHenry) was then injected intradermally to produce capillary paresis. No constant changes were found. Altogether 80 cases were studied in this manner.

One of us (A. C. I.) then suggested applying the cuff of a sphygmomanometer around the arm, with a pressure of about 40 millimeters of mercury enough to cut off effectively the venous return. By increasing the pressure in the capillaries and arterioles in this manner the factor of "capillary tonus" might be eliminated. This was done with most gratifying results.

It was found in a large number of normal individuals (115 cases) that very little difference existed between the Duke method and the modified method with venous pressure. In general, the latter gave somewhat longer readings and an increased volume of bleeding as demonstrated by the total area of the drops on the filter paper. After many trials the upper limit of normal for the venous pressure bleeding time was fixed at 240 seconds; it was rarely over 180 seconds. But, when the method was tried on a number of cases of jaundice it was found that often when the Duke's bleeding time was normal the venous pressure bleeding time was definitely prolonged. These cases with a prolonged venous pressure bleeding time were almost always found to be the cases that bled, either spontaneously or after

operation. In the following study of 810 pathological cases, this fact was demonstrated repeatedly. We are not prepared to say just what is the mechanism involved (blood chemical studies of diffusible calcium were made and will be reported separately) but we do feel convinced that the method is of distinct value in predicting a hemorrhagic diathesis in jaundice.

THE EFFECT OF VIOSTEROL IN JAUNDICE¹

R. W. McNEALY M.D., F.A.C.S. P. F. SHAPIRO M.D. AND P. MELNICK, M.D. CHICAGO, ILLINOIS
 From the Departments of Surgery and Physiology, Northwestern University Medical School and the Departments of Surgery and Pathology of the Cook County Hospital

THE bleeding tendency in jaundice is undoubtedly related to the degree of liver damage. The mechanism of this relation is obscure but the clinical facts are obvious. The venous pressure bleeding time, or "Ivy" bleeding time (as we have named it) is, therefore in a sense a measure of the degree of liver damage.² That this is true is also brought out by a study of other types of liver damage without jaundice. The Ivy bleeding time is prolonged in many cases of cirrhosis of the liver, in cases of chronic cholecystitis with associated liver damage etc. Cases with liver injury, then formed the bulk of those selected for study.

Dr. R. H. Jaffe suggested to us that a possible explanation for the bleeding tendency in cases of obstructive jaundice was that because of the deficiency of bile in the gastro-intestinal tract, there was a failure in absorption of fat soluble vitamins particularly vitamin D. As this work was being completed a publication appeared from the University of California which confirmed this suggestion. Greaves and Schmidt proved that in the absence of bile from the intestinal tract little or no vitamin D is absorbed. In non-obstructive jaundices or in any liver deficiency with a marked decrease in biliary intestinal content the vitamin D absorption is not completely inhibited but is definitely impaired. The exhibition of large doses of viosterol or the administration of bile salts with it, we thought might correct this deficiency.

The liver stores vitamin D and apparently utilizes it in its hemostatic functions (1, 4). Many reports have been recently published which demonstrate the profound effect of vitamins on the various blood coagulating factors (Kugelmass and Samuel 9, Woehliisch, Sherif and Baum, Lopez, Cramer and Drew and others). In particular the effect of vi-

tamin D in favorably altering these factors and in reducing the bleeding and coagulation time and bleeding tendency in various conditions, has been frequently reported (Phillips, Robertson, Corson and Irwin, 12, Selye, Sanford, Gasteyer and Wyat 15, Brougher, Richardson, Du Plessis, Kugelmass 8, Sincock, Shelling, Kaminsky and Davidson, Hess, Lewis and Rirkin 5, Jones, Rapaport and Hodes 6, Massengale and Nussmeier 11, Rohmer and Maryssael 14 and others). The effect of vitamin D in increasing the calcium content of the blood has received particular attention and the relationship between blood calcium and blood coagulation is widely accepted. Enteral exhibition of calcium however has only a slight effect on blood calcium and parenteral administration has only a transitory effect. Viosterol it was thought by its indirect action on calcium metabolism would have a more prolonged and decisive effect in favorably influencing the blood coagulation and bleeding time.

A review of the literature revealed, however that the evidence for the relationship between blood calcium and blood coagulation and for the relationship between vitamin D and blood calcium was in many cases indecisive and contrary. We decided therefore to study in our own cases the relationship between viosterol administration and blood calcium (this work will be reported in a separate paper) and in the meantime to determine clinically whether viosterol actually would decrease the bleeding tendency of cases of jaundice or hepatic insufficiency.

Eight hundred and ten unselected cases at the Cook County Hospital were studied in a period of 14 months. Almost all the jaundiced patients who entered the hospital during this period were studied namely those with common duct stone, cirrhosis of the liver with jaundice, toxic hepatitis, catarrhal jaundice, primary and metastatic carcinoma of the liver.

See Ivy, A. C., Shapiro, P. F. and Melnick, P. The bleeding tendency in jaundice. Surg. Gynec. & Obst. 1935 60 751-754.

This work was aided by grant from Mead Johnson and Company.

carcinoma of the extrahepatic bile ducts and of the head of the pancreas etc. Another large group included patients with liver damage but without jaundice such as cirrhosis of the liver without jaundice chronic cholecystitis, and cholelithiasis, etc. A miscellaneous group of jaundiced patients included pneumonia with jaundice cardiac decompensation with jaundice, etc. In addition various types of miscellaneous patients were studied mainly as controls such as various types of blood dyscrasias and anemias, purpura, tonsil cases with bleeding history etc.

The patients were grouped broadly into surgical and medical patients. In the surgical patients the practical aspect of postoperative bleeding was a measure of the effect of viosterol in addition to the lowered Ivy bleeding time. In the medical cases, the Ivy bleeding time was of chief value although cessation of spontaneous bleeding from the gastro-intestinal tract or other sources was also an indication of viosterol effect. In general the average dose of viosterol was 30 drops of 250d three times a day. In cases with acholic stools bile salts were also administered to insure the absorption of vitamin D. In addition calcium and glucose were sometimes administered orally or intravenously. Thus administration was irregular and was done in the control cases in about the same proportion as in the definitive group. For a time viosterol 10,000 was given to some patients but no difference could be noted in its action and it was discontinued. In general where the bleeding time was not prolonged no viosterol was given the course was usually uneventful. About one-third of the patients with a prolonged bleeding time, unselected, were used as controls and were not given viosterol.

SURGICAL CASES

SURGICAL CASES
1 Chronic cholecystitis and cholelithiasis
Among the surgical patients 254 were patients
with chronic cholecystitis and cholelithiasis
upon whom a cholecystectomy was performed.
In this group there were 219 (19 colored and

The weekend and other drugs
by Mabel Johnson and Company

AND OBSTETRICS

200 white) who showed no bleeding tendency in any of the preliminary tests. They included 30 men and 189 women. No viosterol was given. In the whole group there were only 3 deaths, all from extrahepatic complications. One patient died of cardiac decompensation 2 weeks after operation, and 2 of bronchopneumonia 10 days after. One patient ran a stormy postoperative course. The rest, 215 patients, made an uneventful recovery. The Ivy bleeding time thus seems to have good prognostic value for when it is normal. Good results can be expected and viosterol is not indicated. Thirty five or 13.7 per cent of the patient (Table I) in this group (Table I) had a preliminary tendency to bleed.

g time thus seems to be normal. Good results are expected and viosterol is not indicated. Thirty five or 13.7 per cent of the patients (3 men and 32 women) in this group (Table I) showed a bleeding tendency on the preliminary tests. The Duke bleeding time averaged 120 seconds well within the normal range but the Ivy bleeding time averaged 320 seconds, quite above the normal upper limit of 240 seconds. Nineteen of the 35 patients gave a history of abnormal bleeding. The icteric index averaged 11. Of these 35 patients with a bleeding tendency 24 were given viosterol for from 4 days to 2 weeks before operation in doses of 30 to 60 drops three times a day. After this therapy the Duke bleeding time averaged 80 seconds, the Ivy bleeding time dropped to 130 seconds. Twenty two of these patients made uneventful postoperative recoveries and two ran stormy postoperative courses. There were no deaths.

As a control series, 11 of the patients were not given vosterol. Without vosterol preparation the Duke bleeding time before operation averaged 132 seconds, and the Ivy bleeding time averaged 346 seconds, still well above normal. In these cases there was no spontaneous bleeding, and 10 ran on a blood transfusion.

Thus, in these cases there was no spontaneous improvement in the bleeding time. One patient died in cholemia, and 10 ran stormy postoperative courses requiring blood transfusions and 4 to 6 weeks' stay in the hospital. There were no smooth recoveries. Here too the bleeding time was seen to have progressive improvement. When it is increased trouble can be expected unless it is first reduced by vascular therapy.

It is significant that at operation no unusual difficulty with haemostasis was noted even in the control cases. The patients went bad

TABLE L—SURGICAL GALL-BLADDER CASES WITH BLEEDING TENDENCY

Case number	Sex and color	Age	Icteric index	Bleeding tendency	Duke bleeding time	Ivy bleeding time	Viosterol	After viosterol					Results

SURGERY GYNECOLOGY AND OBSTETRICS

8 to 24 hours after operation. It occurred to us here that the reason for this is that jaundiced patients clot as quickly as normals, but that their clots are fragile, and the postoperative retching etc. breaks them loose. We have spent a great deal of time in studying the clots of these patients. The increased fragility of their clots in comparison with normal clots is obvious, but we have as yet been unable to devise an instrument to record this fragility accurately.

2 Common bile duct stone. Sixty-four patients with common bile duct stone were operated upon. Of these 27 men and 19 women showed no bleeding tendency. Their icteric index ranged from 16 to 150; their ages from 24 to 68. None of the 27 received viosterol except patient 26. All made uneventful postoperative recoveries except patients 26 and 24. Therefore in patients with normal liver and smooth spontaneous recovery bleeding time can usually be expected without viosterol. Patient 24 was a white woman 46 years old who had an icteric index of 35, no bleeding history and a bleeding time which was just within normal limits. She was in excellent general condition. She was not given viosterol but the night before operation was given 5 cubic centimeters of 10 per cent calcium chloride intravenously. She died suddenly 1 hour after the injection. He had an icteric index of 130. There was no bleeding history. He had a normal bleeding time, but was in poor general condition. For this reason he was given 30 drops of viosterol three times a day for 10 days. He died 4 days after operation in cholemia.

Thirty-seven or 57 per cent of the patients with common duct stone (11 men and 26 women) had an abnormally prolonged bleeding time. The Duke bleeding time averaged 125 seconds, but the Ivy bleeding time averaged 330 seconds. The icteric index averaged 58. Twenty-four of the 37 patients were given viosterol. The bleeding tendency stopped in all except patient 762. The Duke's bleeding time dropped in from 1 to 2 weeks to an average of 65 seconds, the Ivy bleeding time to 120. There was only 1 death patient 762 and only 1 stormy postoperative course.

As a control series, 13 of the 37 patients were not given viosterol. The bleeding tendency persisted in 11 of these 13 patients, the Duke's bleeding time rose to an average of 140 seconds, the Ivy bleeding time rose to an average of 385. There were 5 deaths, 8 stormy postoperative courses and no uneventful recoveries. This stands in striking contrast to the group with prolonged bleeding time who were given viosterol (Table II).

3. Surgical malignancies. Twenty-four surgical patients with carcinoma of the liver or of the extrahepatic bile ducts were studied. There were 16 men and 8 women (4 women) of these patients (10 men and 4 women) showed no bleeding tendency. Their ages varied from 40 to 72. No viosterol was given. Thirteen of the fourteen had exploratory laparotomies. One patient was in very poor condition when operated upon and died a few hours later. The rest made uneventful postoperative recoveries. One patient had a cholecystogastrostomy with an uneventful recovery.

Ten or 41 per cent of the patients (6 men and 4 women) showed a bleeding tendency (Table III). Six gave a history of bleeding and 4 gave a history of bleeding. The Duke bleeding time averaged 120 seconds, the Ivy bleeding time averaged 56. The Duke's bleeding time averaged 430 seconds. Eight of the 10 patients were given viosterol. The Duke's bleeding time within from 5 to 12 days dropped to an average of 75. The Ivy bleeding time to 190 seconds. Two patients on viosterol retained their bleeding tendency. One died in cholemia. The other ran a stormy postoperative course. A third patient was relieved of his bleeding tendency but died of cardiac decompensation 2½ weeks after operation. Five of the 6 whose bleeding tendencies were reduced made uneventful postoperative recoveries. As a control series, 3 patients remained un-

changed. The bleeding time remained uneventful. Both died in cholemia. In these patients, too, the same general relationship holds between the bleeding time and the prognosis. Also the effect of viosterol in keeping down the bleeding time and bleeding tendency for a time was noted. However where the liver is hopelessly damaged and risk-

She was put on viosterol but transfusion was also given. Her bleeding time dropped to 15.0. The platelet count rose to 150,000. Splenectomy was unnecessary.

died by carcinoma nothing will help it. We were able to follow the gradually advancing destruction of the liver by the gradually increasing bleeding time and the failure of the patient to respond to viosterol.

4 Miscellaneous surgical cases. There were 2 patients with liver abscess. Neither showed a bleeding tendency. No viosterol was given. They were drained surgically and made uneventful recoveries. One patient with biliary cirrhosis, patient 393, was operated. She was 33 years old and had an icteric index of 150 and no bleeding tendency. She was not given viosterol. While in the hospital her Ivy bleeding time increased from 160 to 300. She was explored at that time. The postoperative bleed course was stormy and the prolonged bleeding time continued for 4 weeks when she began to recover slowly. One patient with a splenic anemia was operated upon. She was 55 years old and had a very high bleeding tendency (380 seconds Duke, 460 Ivy). No viosterol was given. Splenectomy was done. The patient died 1 week later with recurrent hemorrhages. One patient with a thrombocytopenic purpura, patient 764, had a Duke bleeding time of 510 seconds and an Ivy bleeding time of 670 and a platelet count of 70,000.

She was put on viosterol but transfusions were also given. Her bleeding time dropped to normal and the platelet count rose to 150,000. Recovery after splenectomy was uneventful. During the course of the year 29 tonsil patients were found (out of about 5,000 operations) who gave a bleeding history (15 males and 14 females). Their ages varied from 4 to 31 years. Only one of these, however, showed a slightly prolonged bleeding time (260 Ivy). No viosterol was given to any case. All even the latter made uneventful recoveries. There were no cases of serious bleeding other than a few cases on the basis of definite surgical injury to larger vessels. There were no deaths. Because of inadequate bleeding material nothing can be said regarding the use of viosterol before tonsillectomy.

MEDICAL CASES

1 Chronic cholecystitis and cholelithiasis. Eighty-two patients with chronic gall-bladder disease entered the hospital with symptoms of biliary colic, acute gastro-intestinal upsets, or chronic dyspepsia. There were 11 men and 71 women. Of these only 1 showed a bleeding tendency. No viosterol was given. All recovered promptly from their admission symp-

TABLE IV—MEDICAL COMMON BILE DUCT CASES

Case number	Sex and color	Age	Icteric index	Bleeding	Duke	Ivy	Viosterol	After viosterol			Result
								Bleeding	Duke	Ivy	
534	♀	26	59		90	470	30 drops t i d 2 wk + bile salts wk.	0	90	150	Improved, refused operation
703	♀	30	19		90	41	30 drops t i d 2 wk + bile salts 2 wk	0	70	190	Improved, refused operation
704	♀	30	62	+	70	450	30 drops t i d 10 days + bile salts 10 days		50	140	Improved, refused operation
676	♂	43	32	0	30	240	Calcium only		60	90	Slow improvement, refused operation
705	♀	23		++	160	440	No viosterol	++	200	430	Died 2 days
783	♀	45	38	0	30	300	30 drops t i d 2 wk + bile salts	0	80	200	Refused operation
781		48	++	0	30	80	No viosterol	±		170	Refused operation

toms. Operation was not advised for the time being in many of the cases, in the remainder, the patients refused operation and left the hospital. One patient, 355, a man 47 years old entered the hospital with an acute cholecystitis. He had a bleeding history and a prolonged bleeding time (Duke 230 seconds, Ivy 550). He was not given viosterol. Operation was advised but he refused and left the hospital.

2 Common duct stone. Fourteen patients with common bile duct stone were studied who did not come to operation. There were 8 men and 6 women. Seven patients showed no bleeding tendency. They had an icteric index of 27 to 70. No viosterol was given. All made a spontaneous temporary recovery from their jaundice and gastro-intestinal symptoms.

Seven patients manifested a bleeding tendency (Table IV). Two gave a history of bleeding, Duke's bleeding time averaged 90 seconds, Ivy bleeding time 400 seconds. The icteric index averaged 38. Four of these were given viosterol and bile salts. The Duke bleeding time within 1 to 2 weeks averaged 70, the Ivy bleeding time dropped to 140 seconds. All 4 recovered. One patient received calcium only. She improved slowly. Two patients received no medication. The bleeding time remained unchanged in 1 and the patient died. In the other it grew steadily longer and the patient steadily worse. The prognostic value of the Ivy bleeding time and efficacy of viosterol in improving prognosis is shown in these as in the surgical patients.

3 Empyema of gall bladder. One patient with empyema of the gall bladder, patient 356,

a man 44 years old was admitted in poor condition. Viosterol was not tried. He died in 2 days. Another similar patient, 601, was prepared with viosterol. She began to recover spontaneously and refused operation. The correct diagnosis in this case is in question.

4 Catarrhal jaundice. Fifty-one patients with catarrhal jaundice were studied. 36 men and 15 women. Thirty-six patients showed no bleeding tendency. They had an icteric index of from 18 to 100. Their ages varied from 15 to 55. No viosterol was given. All recovered promptly within 2 weeks.

Fifteen patients, or 29 per cent, had a prolonged bleeding time, the Duke bleeding time averaged 115 seconds, the Ivy 330 seconds (Table V). Twelve gave a history of abnormal bleeding. The icteric index averaged 58. Twelve of the 15 were given viosterol. The bleeding tendency stopped in all within 1 to 3 days. The Duke bleeding time dropped within 3 to 6 days to an average of 70 seconds, the Ivy to 100 seconds. All 12 recovered promptly within from 5 days to 2 weeks. Three of the 15 were not given viosterol. One was ill for 7 weeks, 1 for 6 weeks, and only 1 recovered with usual promptness. Although catarrhal jaundice is a self-limited disease, it seems that when a prolonged Ivy bleeding time clouds the prognosis, viosterol is of value.

5 Cirrhosis of the liver. There were 104 patients with cirrhosis, 56 men and 48 women. Most of these were periportal cirrhosis, a few were biliary. Only 4 of the patients were colored.

Forty-seven patients showed no bleeding tendency. No viosterol was given, but the

109	♀	30	84								

patients were under observation in the hospital for from 3 to 6 weeks. Their icteric index ranged from 7 to 94 their ages from 36 to 62. Forty two of these patients were stationary while under observations or improved slightly. One patient, 468, a man 38 years old had a low bleeding time but was nevertheless moribund on admission. He died the next day.

Fifty seven patients, or 54 per cent with cirrhosis had a prolonged bleeding time. The Duke bleeding time averaged 128 seconds, the Ivy 350 seconds. Thirty-eight of the 57 cases gave a history of abnormal bleeding. The icteric index averaged 44.

Thirty of the 57 patients were given viosterol (Table VI). Six of them died in the course of 3 to 6 weeks although none was moribund on admission. The bleeding tendency of these 6 did not abate on the administration of viosterol. The Duke bleeding time rose to 190 the Ivy to 460. Two patients were stationary, one made slight improvement. Four patients improved moderately and 17 patients improved markedly while under viosterol treatment. In the 24 patients in this group on viosterol who survived the bleeding tendency subsided in from 1 to 4 weeks. The Duke time fell in from 1 to 4 weeks to an average of 75 seconds, the Ivy to 150 seconds. In 2 of the patients who were improving the viosterol was stopped. One of them became rapidly worse but is still alive the other died.

Twenty-seven of the 57 patients with bleeding tendency were not given viosterol despite their prolonged bleeding time (Table VII). There were 14 deaths, but 9 patients were moribund on admission therefore only 5 cases can be counted to compare with the cases receiving viosterol. The striking contrast was that 9 of the control patients ran a progressive downhill course. 1 was stationary, 1 showed a slight improvement, and only 1 showed a marked improvement when viosterol was withheld. In these last 13 patients who are still living the Duke bleeding time averaged 90 seconds, the Ivy time remained at 310.

It seems that in cirrhosis of the liver with a prolonged bleeding time, if the process is early or slow in its progress, viosterol has some

TABLE VI.—CIRRHOSIS CASES WITH BLEEDING TENDENCY AND VIOSTEROL

27 women Forty five of these patients showed no bleeding tendency Thirty-eight of them were secondary carcinomata of the liver 1 was a carcinoma of the gall bladder 3 were carcinoma of the head of the pancreas, and 3 were carcinomata of the common bile duct No viosterol was given All were under observation for 2 to 7 weeks All were either stationary or showed only a slow decline except 2 patients, 404 and 794. Patient 404 was a man 60 years old with an icteric index of 145 He had a low bleeding time but died apparently of cardiac decompensation Patient 794

died although the bleeding time was normal. Twenty three of the 68 patients showed a bleeding tendency (Table VIII). There were 15 secondary carcinomata of the liver, 4 of the common bile duct, 3 of the pancreas, and 1 of the gall bladder. The Duke bleeding time averaged 150 seconds the Ivy 355. Eight of these were given viosterol. Three died but was moribund when treatment was started. Two became steadily worse, 2 remained unchanged and 1 improved slightly. In the group the Duke bleeding time remained at 120, the Ivy at 330.

704	F	70	Carcinoma of common duct	4+	+	30	30	No viosterol				Died

Fifteen patients were not given viosterol. Twelve died, but 5 were moribund on admission leaving 6 deaths to compare with 2 of the other series. One patient became slightly worse, none showed even slight improvement. The Duke bleeding time remained at 130, the Ivy at 350. Viosterol was of no demonstrable value in these cases.

7 Cardiac decompensation with jaundice. There were 9 patients, 5 men and 4 women. Seven of them showed no bleeding

tendency. All gradually improved under the usual cardiac therapy. One case was given viosterol but made no better improvement than the others. Two patients had prolonged bleeding time. One patient, 266, a man 41 years old, had an icteric index of 46, a Duke bleeding time of 150 and an Ivy bleeding time of over 600 seconds. He was moribund on admission. Viosterol was not given. He died the next day. One patient, 414, a man 57 years old, with an icteric index of 36 and an Ivy

TABLE IX.—TOXIC HEPATITIS WITH BLEEDING TENDENCY

Case number	Sex and color	Age	Diagnosis	Bleeding time	Ivy bleeding time	Duke	Ivy	Viosterol	After viosterol			Result
									Bleeding	Duke	Ivy	
107	F	58	Toxic hepatitis	65	+	30	130	No viosterol + wk.		70	280	Dying worse
								No viosterol wk.	±	100	340	Getting worse
								30 drops t. i. d. wk.		70	270	Improving
								60 drops t. i. d. wk.		70	70	Recovered
78	F	33	Toxic hepatitis	58	+	100	130	60 drops t. i. d. wk.		80	70	Recovered
603	F	18	Toxic hepatitis	100		60	150	30 drops t. i. d. 10 days			70	Recovered
746	F	27	Toxic hepatitis	60	+	30	260	3 drops 10, 20, 30 t. i. d. wk.			60	Recovered
120	F	34	Toxic hepatitis		+	100	300	No viosterol		70	70	Recovered
57	F	24	Toxic hepatitis	35		120	260	No viosterol		70	180	Recovered
766	F	20	Toxic hepatitis	++	+	100	600	No viosterol	+		300-1	Worse
3	F	47	Toxic hepatitis	80		30	300	3 drops 10, 20, 30 t. i. d. wk.			60	Improved, recovered
			(Second admission)	58	++	110	410	30 drops t. i. d. wk.	0		120	Recovery

bleeding time of over 600 was given large doses of viosterol (60 drops three times a day). He died in 3 days. Viosterol was of no value in these cases.

8 Toxic hepatitis. Fourteen patients with toxic hepatitis were studied, 4 women and 10 men. Six showed no bleeding tendency and recovered promptly. Eight had prolonged bleeding times (Table IX). The Duke bleeding time averaged only 88 seconds, but the Ivy averaged 310. Five were given viosterol. Three were not. All recovered promptly. The Duke bleeding time decreased to 65 seconds, the Ivy dropped to 110. Of course, no effect from viosterol was demonstrated. However, 1 patient, 107, a colored woman 58 years old had a low bleeding time on admission. Viosterol was not given. She began to grow worse. Viosterol was then given, she improved rapidly. Patient 787 had a prolonged bleeding time which dropped to normal under viosterol therapy. Treatment was stopped and he left the hospital. He returned 1 month later with recurrent hemorrhages and prolonged bleeding time. Viosterol again brought his bleeding time down to normal and stopped his bleeding.

9 Miscellaneous. There were 15 patients with jaundice with miscellaneous conditions such as pneumonia, portal thrombophlebitis, ascending cholangitis, pyelonephritis, miliary

tuberculosis and Bant's disease (Table V). Viosterol was given in most of the cases in which the Ivy bleeding time was prolonged. The results seemed to depend largely on the basic condition rather than on the jaundice. At any rate, there were too few similar cases in this series to warrant conclusions.

10 Pernicious anemia. Seventeen patients with pernicious anemia were studied, 7 women and 10 men. Eleven had no bleeding tendency and showed a prompt remission under liver therapy. Six patients showed a bleeding tendency (Table VI). The Duke bleeding time averaged 150 seconds, the Ivy 340. Four were given viosterol and 2 were not. All however showed a prompt remission. The Duke bleeding time fell to 60 seconds, the Ivy to 115.

11 Leucemia. There were 11 patients with leucemia. Three of these chronic myeloses had no bleeding tendency. Viosterol was not given. They improved slightly while under observation and left the hospital. Eight of the leucemias showed a marked bleeding tendency (Table VII). The Duke bleeding time averaged 380 seconds, the Ivy 500 seconds. Six of the patients were given viosterol, 2 were not. The bleeding time went even higher in all and all patients died. Viosterol was of no value in these cases.

TABLE X.—MISCELLANEOUS MEDICAL JAUNDICED CASES WITH BLEEDING TENDENCY

Case number	Sex and color	Age	Diagnosis	Icteric index	Bleeding	Date	Ivy	Viosterol	After viosterol			Result
									Bleeding	Date	Ivy

12 *Secondary anemia* Fourteen patients with secondary anemia were studied. Six of them showed a prolonged bleeding time (Table XIII). The results of viosterol therapy, however were inconclusive.

13 *Purpura* There were 13 patients with purpura, 3 patients with toxic purpura, and 1 of septic purpura showed normal bleeding time. Viosterol was not given, all recovered promptly. Nine patients had prolonged bleeding times (Table XIV). Of these 1 case of septic purpura improved, while another similar case did not improve under viosterol therapy. Two patients with toxic purpura were given viosterol and recovered. Of the 6 patients with thrombocytopenic purpura, 2 were not given viosterol. They grew slowly worse. Two were given viosterol, 1 gradually

improved, the other died. The fifth case 119, came in bleeding very copiously. Whole blood injections controlled the hemorrhages, and the patient slowly recovered after a 4 weeks' illness. Then he had a recurrence. This time viosterol was given without blood injections, he stopped bleeding in 3 days and remained well while under observations for over a month. The value of viosterol was not demonstrated in these cases. The one prompt remission was gratifying but lack of duplication in other cases renders conclusions unjustifiable.

14 *Endocarditis* Four patients with endocarditis were studied. One case of rheumatic endocarditis with no bleeding tendency improved spontaneously. The three patients with malignant endocarditis showed a marked

bleeding tendency. Two were given viosterol one was not all died.

15 Other miscellaneous patients. There were 11 miscellaneous patients with hæmophilia, Bantus disease, scurvy, pellagra, tularæmia, ascites etc (Table XV). Viosterol was given to all patients with a bleeding tendency but there were too few similar cases to warrant conclusions. One patient with dermatographism had no bleeding tendency but was given viosterol to observe its effect. There apparently was no effect. The patient had a severe attack of hives while under treatment.

It is interesting to note that in 5 apparently normal individuals who were found to have a prolonged bleeding time (Table XV) the

bleeding time returned to normal after from 2 to 5 days of viosterol administration.

SUMMARY AND CONCLUSIONS

There is no single method of predicting a bleeding tendency which is applicable to all types of hæmorrhagic diatheses. In the various types of bleeding dyscrasias, it is probable that various factors are responsible and that different tests are required to demonstrate the bleeding tendency in each. Thus, in purpura the platelet count in hæmophilia the Howell method of coagulation time determination are the most reliable methods of predicting a bleeding tendency. In jaundice or in any liver deficiency neither of these methods nor the Biffi nor Bogg, nor Lee and White method of

SUMMARY AND CONCLUSIONS

There is no single method of predicting a bleeding tendency which is applicable to all types of hemorrhagic diatheses. In the various types of bleeding dyscrasias, it is probable that various factors are responsible and that different tests are required to demonstrate the bleeding tendency in each. Thus, in purpura the platelet count, in hemophilia the Howell method of coagulation time determination, are the most reliable methods of predicting a bleeding tendency. In jaundice or in any liver deficiency neither of these methods nor the Biffi nor Bogg nor Lee and White method of

2 Before exploration for probable malignancy in and about the liver the same results apply unless liver damage is too far advanced

3 In medical cases of gall bladder disease or common bile duct stone viosterol therapy is also indicated if the Ivy bleeding time is prolonged. It then has some value but its effect is not as striking as in the surgical cases

4 In catarrhal jaundice viosterol hastens recovery only in case of prolonged bleeding time

5 In cirrhosis of the liver viosterol is indicated in patients with a prolonged Ivy bleeding time and is of value provided the hepatic damage is not too far advanced or too rapid in its progress.

6 In the medical cases of malignancy in and about the liver viosterol has no particular therapeutic value

7 Viosterol was of no demonstrable value in the miscellaneous jaundices due to cardiac decompensation pneumonia, toxic hepatitis, Banti's disease, portal thrombophlebitis etc.

8 Viosterol was of no particular value in the bleeding tendencies resulting from the blood dyscrasias such as pernicious anemia, leucemia secondary anemia hemophilia, etc., nor was its value sufficiently demonstrated in our small series of purpura, scurvy endocarditis and miscellaneous bleeding cases

9 Before tonsillectomy bleeding histories may be checked by bleeding time determinations but our series of positive bleeders was too small to warrant conclusions

10 The data on the relationship of the prolonged Ivy bleeding time and the effects of viosterol to blood chemistry changes will be reported in a separate communication

MECHANICS OF THE PHYSICAL SIGNS IN LOWER TRUNK INJURIES

LEOPOLD BRAHDY M.D. NEW YORK, NEW YORK

From the Bureau of Workmen's Compensation, Office of the Corporation Counsel of the City of New York

MOST injuries of the lower trunk involve the soft tissues only are not demonstrable in roentgenograms, and must be studied clinically (10). The diagnosis of the lesions in which roentgenograms are negative is important from a therapeutic standpoint. The various results of trauma call for different treatment and thereby necessitate differential diagnosis. In compensation cases accurate diagnosis is important in order to distinguish between the malingerer and the honest claimant.

This paper is limited to the lower trunk injuries which involve the ischiogluteal bursa, the sciatic nerve, the ligaments and joints of the lumbar spine, the sacrum, the coccyx, and the hip. In all these injuries there is pain on motion of the trunk and of the extremities. To ascertain what the condition is, to differentiate it from hysteria and from malingering we must analyze the pain producing and the pain relieving motions. A specific pain producing motion is usually named after the man who originally described it as a sign of one pathological condition. Thus flexion of the straight leg at the hip joint elicits pain in the dorsum of the thigh in sciatic neuritis, and is called Lasègue's (9) sign. The same motion elicits pain in the sacro-iliac region in sprain of the sacro-iliac ligaments and is then called Goldthwaite's (8) sign. Outward rotation of the semiflexed thigh may be limited and pain ful in lesions of the hip joint and is then called Patrick's or Lagùère's sign. But the Patrick-Lagùère motion may produce pain in sacro-iliac and in lumbar sprain. We have learned that with few exceptions the signs are not pathognomonic. Errors in diagnosis or failure to gauge the extent of the disability frequently are due to a misunderstanding of the physiology of the body motions used in the examination. The purpose of this article is to describe the physiological basis of the examination. A brief review of the pathology is first presented.

Sprain of ligaments. The function of a ligament is to limit motion of a joint. It follows that the ligament must be just long enough to permit the physiological motion and to endure a certain amount of stress when there is any force attempting to exceed the physiological motion of the joint. In contradistinction to muscle tissue, ligaments have a minimal power of elongation. When a force is sufficient to overcome the resistance of the ligaments, there is an injury to the ligamentous tissue which we call a sprain. The longer the ligament the greater is the degree of motion beyond the physiological required to produce sprain. Where the motion between two bones is very small and the connecting ligaments short, the amount of movement beyond the normal required to strain that ligament is very slight. In a ligament like the lumbosacral, where the amount of physiological motion is small, a sprain can be produced by a motion forcing the ligament to stretch as little as an eighth of an inch. If the ligament is long, as in the ankle joint, it permits a wide range of motion and several degrees of motion in excess of the normal are required to injure the ligament. The severity of sprains varies. Some give mild pain for a few minutes only; others give pain for months.

Pathological examination in the early stages of sprain shows tearing of some of the fibers of the ligament, with bleeding, subsequent examinations show the usual stages of inflammation and repair with scar tissue formation. If there is much scar tissue, its contraction results in shortening of the ligament. The shortened ligament will decrease the range of motion which was possible before the injury.

The bases for diagnosis of sprain of a ligament anywhere in the body are: (1) an area of swelling over the ligament; (2) a definitely localized point of tenderness over the ligament; (3) a spasm of the muscles which prevents stress on that ligament; (4) relief of pain when assuming a position which relieves that ligament of stress; (5) production of pain on

assuming a position which puts stress on that ligament.

In back sprains the swelling is sometimes present in the early stages. More often it is absent, because the ligaments are located beneath the muscle and fat tissue, so that the swelling is not perceptible. For the same reason, the tenderness is not as sharply localized as in the case of sprains of the more superficial ligaments of the extremities. The third, fourth, and fifth criteria of ligament sprain are the same in the back as elsewhere, but assume added importance because swelling and tenderness are unreliable signs.

The diagnosis of sprain is incomplete unless it includes a localization of the involved ligament. Sprains of three sets of ligaments of the lower spine produce signs which clearly differentiate them from one another (1) the coccygeal, (2) the sacro-iliac and ilio-lumbar, (3) the lumbar.

Schmorl has established the importance of the intervertebral disks in the pathology of the spine. If the lesion in some traumatic spine injuries is in the intervertebral disks and not in the connecting ligament the important physical signs must be similar. Functionally the disk is an elastic ligament connecting two vertebral bodies. As in sprain of the other intervertebral ligaments, pain is elicited when these two bodies move on one another. The motions causing or relieving pain will be similar to those of sprain of the true ligaments between the two vertebrae.

Ghormley has recently described injury to the cartilage of the articular joints of the spine as a true traumatic arthritis. He believes that the sudden onset of symptoms with "locking" indicates injury to the cartilage. The occasional sudden relief of symptoms on manipulation is also indicative of an intra articular lesion rather than a ligament sprain. Most authorities believe that traumatic arthritis is an exceptional complication.

The controversy as to whether there is any such thing as traumatic subluxation of the sacro-iliac joint has continued for decades sometimes merrily and often acrimoniously. As there is no direct evidence for its existence, I prefer not to use the term subluxation. However there is no doubt that there is a patho-

logical condition following sprain, the signs and symptoms of which are referable to the area of the sacro-iliac joint. In such cases it is found that any motion or position which puts stress on the ligaments of the sacro-iliac joint elicits pain. Any force that puts stress on the ligaments can also produce that minute motion which we know normally exists in this joint. Can the pain be due to sacro-iliac arthritis? Possibly—but motion so minute as to be demonstrable only in the dissected specimen does not elicit pain in any other joint except in fulminating inflammations. That the lesion is localized in the ligaments is the most reasonable hypothesis. Opinion on the pathology may differ. The signs and symptoms constitute a clear cut clinical entity.

It must be remembered that nearly every motion that puts stress on the sacro-iliac ligaments also puts some stress on the ilio-lumbar ligament. The signs and symptoms which we call the sacro-iliac syndrome, may be due to strain of the ilio-lumbar ligament alone or in combination with strain of the sacro-iliac ligaments. The name sacro-ilio-lumbar sprain is more accurate. Nevertheless the name sacro-iliac syndrome for a combination of physical signs has been in use so long that a change in the name is not desirable.

Synovitis and peri arthritis The synovial membrane is a thin sheet of endothelium like cells which invests the inner side of the capsular ligament of all true joints. Direct trauma (a blow) or indirect trauma (excessive stress on the capsular ligament) may produce an aseptic inflammatory process in this membrane. Synovitis frequently is manifested by an exudate in the joint. Usually the exudate is absorbed completely in time and the joint resumes its normal function. In more severe cases, the exudate is fibrinous and the capsular ligament adheres to the joint surfaces resulting in painful and decreased range of motion. As the synovial membrane is intimately connected with the inner side of the capsular ligament it is not possible to have a traumatic synovitis without some injury to the ligament. The ligamentous injury may resolve before the synovial exudate is absorbed so that clinically only the synovitis is of importance. On the other hand, the injury to the capsular ligament

Fig. 1. Effect of flexion of the thigh on the gluteus maximus muscle. The relation of the muscle to the ischio-gluteal bursa is shown.

and the neighboring ligaments may give serious symptoms so that the amount of joint fluid and its absorption are secondary. The inflammatory reaction to trauma in the joint ligaments constitutes a peri-arthritis. In some joints the presence of fluid is easily demonstrated. In the interarticular joints of the vertebrae in the sacro-iliac and the sacrococcygeal joints such demonstration is not possible. In an occasional case of sprain of the hip ligaments a fullness in the groin suggests fluid in the hip joint. In general the only clinical evidence of synovitis in lower trunk injuries is pain when the involved joint is moved. But pain results from the same motion if there is traumatic inflammation of the capsular ligament of that joint. Clinically no distinction can be made between synovitis and peri-arthritis in these joints. The clinical diagnosis of peri-arthritis, therefore, includes the signs and symptoms of any associated synovitis.

The sacrum and coccyx are separated by a fibro-elastic disk analogous to the intervertebral disk of the movable vertebrae. A synovial joint is sometimes present and at times absent. Traumatic coccygodynia is a sprain of the sacrococcygeal ligaments. Had we any means of knowing that there is a true joint space in a particular case it would be called a peri-arthritis.

Post-traumatic neuritis. The pathology and the mechanism of the production of traumatic neuritis are not definitely known. In 36 of 47

cases examined the history or physical examination indicated that it was a sequel of lumbar or sacro-iliac sprain. This is approximately the proportion reported by others (4). Some authors (13) regard it as a radiculitis, and I believe this is correct. I use the term sciatic neuritis in the sense of an organic affection of the sciatic nerve.

Bursitis. Ischiogluteal bursitis is an inflammation of the lining of the bursa lying on the tuberosity of the ischium under the gluteus maximus muscle. The lining membrane is similar to the synovial membrane of a joint. There is usually fluid in the injured bursa.

EXAMINATION

It is unnecessary to discuss the importance of a general examination to exclude non-traumatic lesions. Many visceral diseases give rise to referred pain in the back. The outstanding characteristic of referred pain is that it is not dependent upon motion or posture of the body (16) in sharp contrast with the pain of lower trunk injuries.

The contours of the body the gait the manner of sitting down and of getting on the examining table must be observed. A spastic lateral lumbar muscle spasm. Besides the deformities, such as scoliosis in anatomical deformities, there are functional changes in posture. The patient will avoid pain by holding his body in such a position as to put the least tension or pressure on the injured tissue. Posture may be defined as the unconsciously assumed position of relief. The postures assumed in some of the lesions under discussion are quite characteristic and should be studied in conjunction with the positions of relief and of aggravation found on examination.

The active and passive motions of the trunk and extremities are tested. The important data to ascertain are which motions elicit and which relieve pain at what angle of motion the first pain is elicited and what degree of limitation of motion is present. In examining sprains of some joints, such as the ankle, it is a simple matter to find the motions which elicit pain and those which relieve it. In examining for lower trunk injuries the motions producing relief and aggravation of the pain are more

complicated, as their effects are indirect. In the following descriptions the motions are grouped to aid in understanding their direct and indirect mechanical effects, the sequence is not the one commonly used in a physical examination. In all unilateral lesions a description of a lesion on the left side is given.

COCYGOODYNIA

Inspection and palpation. In sitting, the patient at times puts his weight on one ischial tuberosity, and at times on the other. When he lies on his back on the examining table there is no tendency to flex the knee or hip.

External pressure over the coccyx produces pain. The pain is usually more marked the nearer the tip of the coccyx the pressure is applied because this means greater leverage for movement at the sacrococcygeal joint. On rectal examination some pain is elicited on pressure over the anterior surface of the coccyx. The sacrotuberous ligament may be palpated on each side as it passes laterally from the sacrococcygeal junction to the ischial tuberosity. Pressure on one or both of these ligaments may elicit pain because their lower fibers are continuous with the sacrococcygeal ligaments.

Determination of pain producing motions. Abduction, rotation, or hyperextension of the thighs or hyperextension of the spine have no effect on the coccyx and produce no pain.

With the patient on his back, the examiner gently flexes one thigh on the abdomen. This motion produces pain accurately referred to the coccyx. Flexion of the other thigh elicits the same pain. How does motion at the hip joint affect the region of the coccyx? The gluteus maximus muscle arises from the ilium, sacrum, and coccyx and is inserted in the upper part of the shaft of the femur. Thigh flexion stretches this muscle (Fig. 1) and pulls on the coccyx. This results in pain analogous to that produced by direct pressure over the coccyx. In the standing position flexion of the trunk produces some pain. Flexion of the trunk on the thighs has the same effect on the gluteus maximus as flexion of the thighs on the abdomen and therefore elicits the same pain. Resumption of the erect posture is even more painful. In resuming the erect posture the

gluteus maximus muscle is not only stretched but there is an active contraction of the muscle resulting in increased pull on the coccyx. With the patient sitting trunk flexion has a similar effect on the gluteus maximus muscle but the contraction of the gluteus maximus is not as strong and the pain though present, is less severe.

The reason for the posture is obvious. The patient sits on one tuberosity to avoid direct pressure on the coccyx. He does not flex the thighs because this results in pull on the coccyx.

ISCHIOGLUTEAL BURSITIS (LEFT)

Inspection and palpation. The patient sits with the weight on the right ischial tuberosity never shifting to the left. There may be some tendency to keep the left thigh less flexed than is normal in the sitting position. When the patient lies on the table the legs are kept straight without any tendency toward flexion of the hip or knee.

With the patient lying face down, there is an area of tenderness over the left ischial tuberosity—none on the right. The inflamed ischiogluteal bursa usually contains sufficient fluid so that it is palpable on gentle pressure over the buttock. There is no tenderness over the region of the sacrococcyx and rectal examination is negative.

Determination of pain producing motions. With the patient lying on his back on the examining table flexion of the left thigh elicits pain which is referred to the buttock, but not definitely localized. Flexion of the opposite thigh produces no pain. Rotation or hyperextension of either thigh has no effect.

The ischiogluteal bursa is located between the gluteus maximus muscle and the ischial tuberosity. Flexion of the thigh stretches the gluteus maximus muscle and therefore puts pressure on the tender ischiogluteal bursa (Fig. 1). Rotation and extension of the thigh put no pressure on the bursa, and therefore have no effect.

In the standing and in the sitting position flexion of the trunk produces the same pain as hip flexion because we have the same stretching of the gluteus maximus muscle with the resulting pressure on the ischiogluteal bursa.

Fig. 2 Flexion of the trunk in standing position. A, Normal trunk flexion by movement of both spine and pelvis. B, Partial flexion of the trunk by pelvic rotation but without movement of the spine. C, Partial flexion of the trunk by spinal motion but without pelvic rotation. The angle of line S-S shows the degree of flexion of the pelvis.

The reason for putting the weight on the affected side in sitting is because of the tenderness of the bursa located directly on the ischial tuberosity. The patient does not flex the left thigh completely because complete flexion stretches the gluteus maximus muscle.

MECHANICS OF NORMAL MOTIONS OF THE TRUNK

Trunk flexion is composed of two simultaneous movements: flexion of the spine and flexion of the pelvis (Fig. 2). In flexion of the spine the normal lumbar lordosis disappears, and changes to a gradual, smooth, convex curve (Fig. 2A). In flexion there is very little movement of the thoracic spine; practically all of the motion taking place in the lumbar portion of the spine. The amount of motion in the lumbar spine can be determined more accurately with a tape as described by McKen- drick. A horizontal line is drawn across the eleventh thoracic vertebra, and a parallel line across the first sacral vertebra. With full lumbar spine flexion the distance between these two lines is increased more than 6 centimeters.

Flexion of the pelvis takes place at the hip joint. As part of the pelvis is below the pivot of motion this movement may be more accurately described as a forward rotation of the pelvis; the axis of rotation is a line connecting the two acetabula. In backward movement of the trunk (extension) the pelvis moves in

the opposite direction and the motion is called backward rotation of the pelvis.

Flexion of the spine and forward rotation of the pelvis contribute about equally to complete trunk flexion. The pelvis can be rotated forward without any motion of the spine (Fig. 2B) resulting in a partial flexion of the trunk. The absence of spinal movement may be voluntary; it may be due to pain on spinal movement or it may be the result of ankylosis of the spine. Partial trunk flexion may be effected by flexion of the spine alone (Fig. 2C). The absence of forward rotation of the pelvis may be due to ankylosis of one or both hips or to pain on forward rotation of the pelvis as in peri-arthritis of the hip joint. We have seen that forward rotation of the pelvis, by stretching the gluteus maximus muscle, produces some pain in ischiogluteal bursitis and in coccygodynia. There may be a tendency to limit pelvic rotation in these two conditions, but there will be no limitation in flexion of the spine.

In every active motion there are two factors—the contraction of one muscle (or group) and the associated relaxation of its antagonist. The normal range of motion, whether passive or active, is usually limited by the structure of the joint surfaces and by the length of the joint ligaments. Some motions are limited by the length of the muscle antagonist. With the patient on his back, passive flexion of the

Fig. 3. Showing the stretching of the hamstring muscles by flexion of one leg. The dotted arc is the arc which would be described by the hamstring muscles if they were not forced to stretch. The solid arc is that described by the points of bony attachment of the muscles. The distance between the two arcs at any point is the amount the muscle must be stretched when the leg is flexed to that point.

straight leg on the abdomen is limited to 90 degrees by the normal hamstring muscles. As the examiner flexes the patient's straight leg the distance between the attachment and insertion of the hamstring muscle must increase (Fig. 3). To visualize this fact we must remember that in flexion the leg revolves with the head of the femur as a pivotal center. The hamstring muscles revolve with their point of origin on the tuberosity of the ischium as a center. Imagine the hamstring muscles detached from their insertion on the upper part of the tibia and fibula. If the leg and the detached muscle are revolved together the free ends of the muscles because their pivotal center is posterior to that of the femur describe an arc proximal to the arc described by the heads of the tibia and fibula as shown in Figure 3. With increasing flexion, there must be an increasing stretching of the muscle, if it is to extend to its point of attachment. When the straight leg has been flexed 90 degrees the limit of elasticity has been reached. Any attempt to flex the straight leg beyond the limit of elasticity of the hamstring muscles produces muscle pain referred to the dorsum of the thigh. This movement tests the elasticity of the hamstring muscle. With the straight leg flexed as shown in Figure 3 the hamstring muscle can be relaxed by bending the leg at the knee joint (Fig. 4) because this brings the origin and the insertion of the mus-

Fig. 4. Showing the decrease in distance from the origin, *O*, of the hamstring muscles to insertion, *I*, on flexion of the knee joint with resulting relaxation of the hamstring muscles.

cle closer together. The thigh can now be flexed completely on the abdomen.

Just as the hamstring muscles limit elevation of the leg when the patient is lying down, so they limit forward rotation of the pelvis in the standing position. Flexion of the knee joint relaxes the hamstring muscles and makes greater pelvic rotation possible. If, however, pelvic rotation is limited by disease of the hip joint, the relaxation of the hamstrings will have no effect.

With one leg in the same position as in Figure 3 the hamstrings could also be relaxed by forward motion of the point of origin of the muscles on the ischium. This means a backward rotation of the pelvis. But with the right leg straight on the examining table the iliofemoral ligament of the right hip is taut and permits only slight backward rotation of the pelvis. When the examiner flexes both legs at the hip as in Figure 5 the hamstrings can pull the ischium forward. Therefore a greater degree of flexion of the legs on the abdomen is attainable when the legs are flexed simultaneously than when one leg is flexed alone. The amount of movement at the hip joints is the same in the 2 cases but with simultaneous leg flexion the whole pelvis rotates backward. In this case the pull of a muscle causes motion in a part not directly moved by the examiner. In motions other than straight leg raising such indirect movement is seldom due to muscle pull but to ligament pull. When a muscle is not spastic or

shortened by disease, it stretches sufficiently to permit as much motion as the length of the ligaments will permit.

The sacrum is part of the pelvis. Backward rotation of the pelvis means a similar motion of the sacrum. This produces a movement of the lumbar spine. The normal concave lumbar curve is first flattened and then becomes convex (Fig. 5). This movement can be demonstrated by the examiner slipping one hand under the concavity of the lumbar spine as the patient lies on his back. When the two legs are flexed at the hip he will feel the pressure of the patient's back as the concavity disappears and the back is flattened. In a preceding paragraph it was shown that but little pelvic motion is possible if the examiner raises one leg alone. It follows that movement of the lumbar vertebrae occurs only when both legs are raised simultaneously. The longitudinal lumbar muscles do not take any part in this motion; they are passively stretched. Normally they are sufficiently elastic so that the vertebrae can move as far as the structure of the ligaments and bones will allow. The sacrum and the lumbar vertebrae are connected to one another by numerous ligaments. As soon as the lumbo-sacral ligaments are a pull on the lumbo-sacral ligaments. As rotation increases the pull is transmitted through the connecting ligaments to the upper lumbar spine. This explains the finding that in lumbosacral sprains pain is elicited on moderate elevation of both legs and by increasing the amount of elevation pain is elicited in sprains of the higher lumbar ligaments.

When we speak of motion of the pelvis it must be remembered that though it moves as one piece the pelvis is not a solid bone. It is composed of three bones: the right and the left innominate bones being united to the sacrum by powerful ligaments. In the erect position most of the weight of the trunk falls on the sacrum and is transmitted through the sacro-iliac ligaments and the innominate bones to the lower extremities. If the sacro-iliac ligaments are strained pain will be felt in the area of the joints in the normal standing position. Although there is some cartilaginous and bony connection between the sacrum

and the ilium the sacro-iliac articulation has a joint space and a minute amount of motion in the joint can be demonstrated in the cadaver. A force exerted through the pelvis (from the trunk to the extremities or from the extremities to the trunk) must be transmitted through the sacro-iliac ligaments. Any motion which tends to rotate the pelvis backward or forward must result in some stress on these ligaments.

In the standing position on flexion of the trunk the pull of the hamstring muscles on the ischial tuberosities tends to pull the pelvis backward. The weight of the trunk exerts a forward stress on the upper sacrum thus tending to rotate the pelvis forward. The resultant of these two opposing forces is a torsion stress on every part of the pelvic ring between the ischium and the sacrum. This ring is composed of bone except at the sacro-iliac joints and the symphysis, and, if the ligaments are sensitive to pull marked pain will result.

With the patient lying prone on the table flexion of the knee stretches the rectus femoris muscle. The origin of this muscle is on the anterior spine of the ilium. The muscle pull tends to rotate the pelvis forward. The stress of the motion is transmitted through the sacro-iliac ligaments to the sacrum and through the lumbosacral ligaments to the lower spine. This movement therefore elicits pain in sprain of either of these ligaments but puts no strain on the sciatic nerve, the ischio-gluteal bursa, or the coccyx.

With the patient again on his back, the heel is placed on the opposite patella, and the thigh is rotated outward and abducted (Fig. 6). In arthritis of the hip joint pain will be elicited because of the movement in the joint. This motion stretches the psoas magnus muscle which takes its origin from the bodies and the transverse processes of the five lumbar vertebrae and is inserted into the lesser trochanter of the femur. By muscle pull on the lumbar vertebrae, slight motion of the vertebrae is produced putting some stress on the intervertebral ligaments. When abduction is complete the hip ligaments are under tension and the pelvis is rotated around its vertical axis (circumduction). This rotary

Fig. 5 The hamstring muscles rotate the pelvis backward to the position shown in solid color. This pelvic rotation flattens the lumbar curve (which is the equivalent of flexion of the lumbar spine). Backward rotation of the pelvis brings the origin of the hamstrings forward thus relaxing the hamstring muscles and permitting greater flexion of the thighs on the abdomen. The arrows pass through the anterior superior spine and the posterior superior spine of the pelvis. S-S First position S-S after flexion of legs with rotation of the pelvis

stress is transmitted through the sacro-iliac ligaments to the sacrum and through the lumbosacral ligaments to the lumbar spine. If any of these ligaments are sensitive, pain will be elicited. This motion puts no stress on the sciatic nerve or on the coccyx.

Let us return to a consideration of stress on sacro-iliac ligaments. With the patient lying face down the knee is raised 12 centimeters from the table. This is approximately the limit of hyperextension at the hip joint and on attempting further motion the stress is transmitted through the hip ligaments to the pelvis. The sacro-iliac ligaments of the same side feel the stress first. It is then transmitted through the sacro-iliac ligament of the same side, via the sacrum to the sacro-iliac ligament of the opposite side. Pain on this motion therefore is elicited on the opposite side, if the opposite sacro-iliac ligament is sensitive.

The patient then lies on the left side with the legs straight, and the examiner hyperextends the right thigh. Stress is felt in the opposite sacro-iliac ligament, but the stress is dissipated by motion of the pelvis with associated increase of the lumbar lordosis. This motion of the lumbar spine is of course transmitted through the lumbar ligaments. If the left leg instead of being straight on the

Fig. 6 The left heel is on the patella of the opposite leg. Outward rotation and abduction of the thigh is done by depressing the left knee. The resulting stretch of the psoas major muscle is shown.

table, is completely flexed at the hip and knee, motion of the pelvis is prevented. The stress of the motion cannot be translated into the movement of the pelvis but is concentrated on the sacro-iliac ligaments of both sides. In this position therefore sacro-iliac pain will be more acute and lumbosacral pain will be mild. When the leg is extended and pelvic motion is possible sacro-iliac pain will be mild while lumbar ligament sprain will elicit marked pain.

LESION OF THE HIP JOINT

Inspection and palpation The patient sits with his weight on the right ischial tuberosity. He sits near the forward part of the chair so that the left hip is slightly flexed but not at a right angle. The posture when lying on the examining table is quite characteristic—the left thigh slightly flexed and everted and the knee slightly bent. Occasionally a slight fullness is noticed below the middle of Poupert's ligament. There may be tenderness at this site. With the left leg straight a blow on the heel may produce pain in the region of the hip joint, this is a valuable sign but seldom present in traumatic lesions.

Determination of pain producing motions With the patient lying on his back, the straight leg of the affected side is rotated outward. This movement elicits pain a sign absent in any of the other conditions with

which we are dealing. This movement stretches the anterior hip ligaments and the anterior portion of the hip capsule. There is not sufficient leverage for the force of this motion to be transmitted to any other joints or structures.

and knee are pressed against the abdomen the pelvis cannot rotate forward and the full force of hyperextension of the left thigh is felt in the ligaments of the left hip.

Although slight flexion and outward rotation is the position of relief assumed by the patient there is pain when flexion with outward rotation is carried further. This is tested by putting the heel of the affected leg on the opposite patella and pressing the knee outward (Patrick Lagure sign). This motion produces pain in peri arthritis of the hip in the same manner as rotation of the straight leg, except that, the force being very much more marked it is positive in cases where the stress of the outward rotation of the straight leg is not sufficient to produce pain. The force of this motion is sufficient to be transmitted to the whole of the pelvis and may produce pain in other conditions besides lesions of the hip joint.

Lesions of the hip joint are often associated with spasm of the psoas magnus muscle. The muscle is stretched by the movement just tested—outward rotation and abduction of the semiflexed thigh (Fig. 6). When this muscle is spastic the range of this movement will be decidedly decreased and painful. This will be because any spastic muscle will not permit the same amount of stretching that the normal relaxed muscle permits. Stretching of any spastic muscle produces pain. Limitation of the range of outward rotation of the psoas flexed thigh is, therefore, indicative of psoas spasm. Psoas spasm however is not diagnostic of lesions of the hip joint. It occurs also in sacro-iliac and lumbar sprains.

The patient now lies on the right (unaffected side) with the right leg straight. When the examiner hyperextends the left thigh, mild pain is produced. The right thigh and leg are now flexed against the abdomen and the left leg again hyperextended. More intense pain is now elicited. This difference in degree of reaction is due to the fact that when the right leg is straight the pull on the anterior ligaments of the left hip produces a forward rotation of the pelvis, thus changing some stress into motion. When the right thigh

The reason for the posture assumed is that hyperextension or marked flexion or marked eversion of the thigh each put stress on the hip ligaments and the position of relief is therefore a position of slight flexion and slight eversion. In sitting this can be done only by putting the weight on the opposite ischial tuberosity.

SPRAIN OF THE LUMBAR SPINE

Inspection and palpation. The normal lumbar lordosis is usually increased especially in the acute stages with lumbar muscle spasm. In the chronic cases the curve may be flattened. There is no tilting of the spine but a mild lumbar scoliosis may be found with unilateral muscle spasm. The marked scoliosis found in sacro-iliac sprain and in acute neuritis is never present.

In the acute stages the muscles on one or both sides of the lumbar spine may be prominent, firm on touch and the skin over the muscles may be very tender. Because of this diffuse tenderness, the pain elicited by pressure over the involved ligament may be masked. In the less acute stages the examiner may elicit tenderness to deep pressure at the sacrolumbar joint or between any two of the lumbar vertebrae. Often the tenderness is localized to one side of the midline indicating that the lesion is in one of the paired ligaments of the lumbar spine. The localization of the tenderness does not vary in the course of the examination. Variable tenderness suggests malignancy or 'neuritic spine' (s).

Determination of pain producing motions. In lesions of the lumbar spine, pain is elicited when the patient assumes any position which

produces motion of the lumbar vertebrae or at the lumbosacral joint because any such motion puts stress on the ligaments. The articular capsules and the ligaments of the bodies and of the arches form a complicated system. It may not be possible to discover which of these ligaments is involved in an individual case. The sprain is often in one of the paired ligaments so that the signs are more marked on one side. However any motion which produces stress on the ligaments of one side will affect those of the opposite side to some extent. The pain on the two sides differs in intensity but not in the type of motion which produces it.

With the patient sitting on a stool, lateral bending of the trunk produces some pain in the lumbar region. Lateral bending is in large part a movement of the lumbar vertebrae, and the stress is felt in the ligaments connecting the vertebrae.

With the patient still sitting on a stool, the examiner grasps the shoulders of the patient and rotates the trunk. Rotation is a movement of the thoracic and cervical vertebrae, and little stress is felt in the lumbar vertebrae until partial rotation has taken place. This motion is therefore painful only in the second half of its range.

Both flexion and extension of the trunk are painful because this is, in part, a movement of the lumbar spine. Full flexion or extension may not be possible because of pain. In flexion of the spine the first movement is at the lumbosacral joint, with lesions of the ligaments connecting the fifth lumbar with the sacrum the pain is therefore felt on very slight motion. With increasing flexion of the spine the fourth then the third, second, and first lumbar vertebrae take part. With lesions higher up, therefore the pain is felt on increasing flexion. The higher the ligaments involved the greater the amount of flexion before pain is produced.

Extension of the spine is examined with the patient prone on the table. The two thighs are simultaneously passively hyperextended. This produces a forward rotation of the pelvis, the stress falling first on the lumbosacral joint. As the thighs are raised more, the stress falls on the ligaments of the

upper lumbar vertebrae. If hyperextension is done by raising the upper trunk instead of the thighs, the stress falls first on the uppermost lumbar ligaments and only with greater extension on the lumbosacral joint. Therefore, when slight extension of the thighs produces pain (lumbosacral sprain) marked extension of the upper trunk is necessary to produce the same reaction. In lesions of the upper lumbar vertebrae, marked extension of the thighs or else slight extension of the trunk are required to produce pain.

When the patient lies on his back and the two legs, with knees straight are raised simultaneously, the motion during the first 20 degrees is a simple movement at the hip joint. With increasing flexion the pelvis rotates backward (Fig 5). The pelvis moves as one piece and this backward rotation of the pelvis means that the sacrum is rotating in the same direction and pulling on the lumbosacral ligaments. If there is a strain of this ligament there will be pain on this motion. With increased backward rotation of the sacrum there is a flattening of the normal lumbar lordosis. The movement of the lumbar vertebrae is analogous to that which takes place in flexion of the lumbar spine. Flexion of the thighs therefore, produces pain in sprain of any of the lumbar ligaments. Moderate flexion will produce pain in lumbosacral sprain. Increasing flexion produces pain in sprain of the ligaments of the higher lumbar vertebrae.

Flexion of the thighs produces pain in the lumbar region only in so far as this position produces backward rotation of the pelvis. There is only slight rotation of the pelvis on flexion of the thighs with the knees bent. When the legs are straight more marked pelvic rotation occurs because of the pull of the hamstring muscles on the ischia. When the examiner's hand is placed beneath the upper part of the sacrum he can determine that the pain is never elicited before the thigh flexion causes some backward rotation of the sacrum. Pain due to rotation of the pelvis is the distinguishing feature of lumbar lesions.

The origin of the pain can be checked by another test. When the patient is lying on the left side with the left knee and hip held in flexion, hyperextension of the right thigh elicits

its but mild pain. With the left leg extended in the anatomical position hyperextension of the right thigh produces much more pain. When the thigh and leg are flexed the pelvis is fixed and the force is not easily transmitted to the lumbar spine but when the left leg is extended the force is quickly translated into motion of the lumbar spine. The results in lumbar sprain are the reverse of those obtained in sacro-iliac sprain.

Outward rotation of the semiflexed thigh will produce pain if the motion is carried far enough because this motion causes a circumduction of the pelvis (rotation on its vertical axis) with its inevitably associated rotation of the lumbar spine. Pain on this motion may also be the result of pull of the psoas magnus muscle on the lumbar vertebra (Fig 6).

MUSCLE SPASM

In the acute stages of lumbar sprain there is spasm of the lumbar muscles. Usually bilateral it may be unilateral. There may be no spasm with the patient at rest but it appears only when the patient flexes the spine or (with the patient on his back) the examiner flexes the thighs.

The normal range of motion of the skeleton is partly dependent on the relaxation of an antagonistic set of muscles. Passive or active motion will be less than normal if the antagonists are shortened by disease or by reflex contraction. This decrease in the range of motion or limitation of motion as it is usually called is important in the diagnosis of trunk injuries. A patient may limit a pain producing motion even though no muscle rigidity is present. This voluntary limitation may be overcome by reassurance and gentleness on manipulation. Voluntary contraction is rarely limited to one specific group of the muscles of the trunk or limb on motion. It may appear after the motion is completed. Involuntary muscle spasm is limited to specific muscle groups, is often (not always) found at rest as well as on motion and is present or develops during motion and not after the motion is completed. Voluntary contraction is not usually a sign of malingering if it occurs with a pain producing motion. If the same reaction occurs with a

motion which should not be accompanied by pain we may conclude that the patient is malingering.

Motion which stretches a spastic muscle will be painful and the range of that motion will be limited. The determination of which motions produce pain and are limited because of muscle spasm is essential for two reasons. First, the presence of spasm in specific muscle groups and its absence in other groups is indicative of certain underlying lesions, are and these underlying lesions, themselves, are diagnosed largely on the basis of the tenderness and painful motions to which they give rise. The motion limited by a spastic muscle is always one which would cause pain in the underlying lesion if the motion were carried to its full range. The limitation of motion and the pain of muscle spasm are always evident before pain is produced at the site of the lesion itself. The pain of muscle spasm is referred to the site of the muscle and not to the site of the lesion.

Lumbar muscle spasm. The sacrospinalis muscle group is chiefly involved in this spasm but it seems probable that the multifidus, the semispinalis, and the small intervertebral muscles also take part. The sacrospinalis muscle is attached below to the sacrum, to the spinous and transverse processes of the lumbar vertebrae, to the lumbar fascia and the eleventh and twelfth ribs. It lies in a groove on each side of the vertebral column. It splits into various groups which are attached above to the lower nine ribs, to the spine, and to the transverse processes of the upper thoracic vertebrae. Some one fasciculus being attached to every bone of the trunk, there is hardly a motion of the trunk which does not stretch part of this extensive muscle group. In extreme spasm, deep breathing may be limited by the fibers attached to the ribs.

Palpation. The patient lies prone on the examining table. The hard sharply outlined mass of a very spastic muscle is easily palpated but it is necessary to train the fingers to feel lesser degrees of spasm. Spastic muscle is always tender. The extent of the muscle involved as well as degree of spasticity varies with the severity of the lesion. In mild cases only a segment may be affected.

Determination of pain producing limited motions due to muscle spasm. In lumbar spasm many motions may be limited, only the more important ones commonly used in diagnosis will be described. Flexion of the trunk is limited in so far as this is a movement of the spine but that part of the movement which is due to forward pelvic rotation is not limited. The limitation of trunk flexion is entirely due to limitation of intervertebral movement. The limitation of lumbar spine movement is the same in sitting as in standing. It follows that the difference between flexion of the trunk in the standing, and in the sitting posture is the same as in the normal individual. Not alone are movements between the lumbar vertebrae limited but also movements between the fifth lumbar and sacrum because the sacrospinalis muscle is attached to the sacrum. Any backward rotation of the pelvis will stretch that muscle. This is the effect of flexion of the two thighs when the patient is lying flat on his back (Fig 5). The backward rotation of the pelvis is more marked if there is forward pull on the ischia by the hamstring muscles, even though there is no hamstring spasm. We have discussed the fact that hamstring muscle pull is greater when the knees are straight. The pain and limitation of hip flexion will therefore, be greater when the knee is straight and will be relieved when the knee is flexed. Because the pelvic rotation is very slight before the end of the first half of trunk flexion the limitation is rarely as marked as in hamstring spasm. As the limitation is due to an effect on the lumbar muscles the pain will be referred to the lumbar region instead of to the dorsum of the thigh. Hamstring tension is somewhat relieved on backward rotation of the pelvis but this motion increases the tension on the lumbar muscles. It has previously been stated that raising the two legs simultaneously produces more pelvic rotation than raising one at a time. In lumbar spasm therefore raising both legs is more painful and limited than raising one leg at a time—in contrast to the result in hamstring spasm.

In unilateral spasm the pain will be present on the affected side only. Spasm of the hamstring muscles is occasionally found in lumbar

lesions but because it is much more common with sacro-iliac sprain and sciatic neuritis it will be described later.

PSOAS MUSCLE SPASM

The psoas muscle may be spastic in lumbar and sacro-iliac ligament sprain as well as in hip conditions. The muscle lies too deep for palpation, spasticity must be determined entirely by indirect means. It is attached above, to the five lumbar vertebrae and is inserted below into the lesser trochanter of the femur.

Determination of pain producing limited motion. With the patient on his back the heel of one foot is placed on the opposite patella. The thigh is then rotated outward and abducted (Fig 6) thus stretching the psoas muscle. When the psoas is spastic this movement elicits pain referred to the pelvic region and the range of the motion is limited.

SACRO-ILIAC SPRAIN (LEFT)

Inspection and palpation. The spine is tilted forward and usually to the right, that is toward the unaffected side. The normal lumbar lordosis is flattened. If scoliosis is present the convexity is to the left (homologous scoliosis). In standing the weight is on the right leg the left knee is slightly bent. There is no eversion of the leg at the hip. Standing is tiring and the patient prefers to sit, putting the weight on the right ischial tuberosity.

The left lumbar muscle may be spastic, occasionally there is spasticity of both lumbar muscles and rarely of the opposite side alone. There is tenderness to the left of the fifth lumbar vertebra and along the posterior border of the ilium, most marked near the posterior inferior spine.

Determination of pain producing motions. The patient lies flat on his back. Flexion of the left thigh with the knee bent, produces a moderate rotation of the pelvis by pull on the hamstring and gluteal muscles. As the pull is on one half of the pelvis while the other half is fixed by the position of the right thigh, the movement produces a rotary stress on the sacro-iliac joint ligaments. When flexion is complete there is some rotary movement of the pelvis on the lumbar spine. The ilio-

Fig 7 Flexion of the straight leg results in a pull on the sciatic nerve trunk. Dorsiflexion of the ankle has the same effect. Flexion at the knee relieves the pull.

lumbar ligament is put under stress by this motion. Thigh flexion produces some pain in all sacro-illolumbar conditions.

When the thigh is flexed with the knee straight, the hamstring muscles come into action at a much lesser angle of thigh flexion. The straight leg is flexed to the point at which moderate pain is produced. In this position bending the knee at right angles results in sudden cessation of pull on the pelvis by the hamstring muscles, and further flexion without pain is possible.

The patient now turns to lie face downward. Hyperextension of the left thigh elicits pain in the left sacro-illiac area. Hyperextension of the right thigh produces no pain at first and on more marked extension pain is produced on the opposite side. Contralateral pain on hyperextension is characteristic of sacro-illiac disease. It was first described by Gaenslen.

With the patient again on his back, the heel of the left foot is placed on the right patella (Fig 6) and the left knee joint pressed downward and outward (i.e. outward rotation of the semiflexed thigh). When this motion is complete there is pressure by the femur on the left half of the pelvis with a shearing stress on the sacro-illiac joint. This motion therefore elicits pain in sacro-illiac ligament sprain. Similar action on the right side will elicit no pain or mild pain referred to left sacro-illiac area.

With the patient lying on the right side the left thigh is hyperextended. This produces stress on the sacro-illiac ligaments but before it can become very great the pelvis

rotates forward. If the pelvis is fixed by complete flexion on the right hip and knee, the same hyperextension produces much more marked stress on the sacro-illiac ligaments. With the patient lying on the left side these maneuvers are repeated. When strain is put on the right sacro-illiac joint there is no pain but when the pelvis is fixed sufficient stress is transmitted to the opposite sacro-illiac area to produce pain.

In the sitting position, flexion of the trunk is painful because the pull of the flexed spine is transmitted through the sacrum to the sprained sacro-illiac ligament. Because of this pain the patient may limit the flexion of the lumbar spine but that part of trunk flexion due to pelvic rotation is not limited.

In the standing position, trunk flexion is more painful than in sitting. In both positions we have the weight of the flexed spine tending to rotate the sacrum forward. In standing with legs straight, we have a second factor—the hamstring muscle pull preventing the full rotation of the pelvis forward. These two forces, one acting on each side of the sacro-illiac joint but in opposite directions, produce a marked stress on the sacro-illiac ligament. The pain and limitation of trunk flexion is, therefore, more marked in standing than in sitting.

Sacro-illiac sprain may be associated with spasm of one or more of three groups of muscles—the lumbar the psoas magnus, and the hamstring muscles.

HAMSTRING SPASM

Inspection and palpation. Spasm of the hamstring muscles cannot be palpated at rest—it is always latent. Examination of the patient as he rests on the table is negative. *Determination of pain producing limited motions.* The patient lies on his back on the examining table. The examiner places his hand under the calf and slowly flexes the hip, the leg being kept straight. The examiner's other hand is on the posterior surface of the thigh to palpate the hamstring muscles. This movement (Fig 3) stretches these muscles and will bring out any latent spasticity. The spasm can be palpated is painful and limits the motion. If the normal muscle is stretched

to its physiological limit at ninety degree flexion of the straight leg, it follows that a spastic muscle will permit less than this normal range of motion. The limitation and pain will be relieved on flexion of the knee for the reasons discussed in the section on "Mechanics of Normal Motion." The difference in the range of motion with the knee flexed and with the knee extended must be more marked when the hamstring muscles are spastic. All other motions that are ordinarily limited when the normal hamstring muscles have been stretched to a maximum will be much more limited when the muscle is spastic. Thus, in the standing position flexion of the trunk, in so far as pelvic rotation is a factor, will be limited and elicit pain in the dorsum of the thigh. Complete flexion is possible when the knees are bent.

In the sitting position because the knees are at right angles there is no limitation in flexion of the trunk. The difference between the range of trunk flexion in standing and in sitting is striking.

A summary of the occurrence and symptoms of muscle spasm may be helpful at this point. In the left hand column of Table I the common lower trunk injuries are listed and on the right the muscles which may be spastic during the acute stages of each lesion. In Table II the motions are listed which are limited and painful in the presence of spasm of each of the three muscle groups.

POST TRAUMATIC SCIATIC NEURITIS (LEFT)

Inspection and palpation. Tilting of the spine is less common than in sacro-lilac conditions, when present it is to the left. Lumbar scoliosis first described by Charcot and Babin ski (1), is found in 80 per cent of cases, the convexity is to the right (contralateral scoliosis). The patient tends to keep the leg everted, the knee bent, and the foot extended

In severe cases the hip is flexed as little as possible. The standing position is more comfortable than sitting.

Tenderness of the nerve trunk may be present but is absent in the majority of cases. What is usually mistaken for nerve trunk tenderness is tenderness of the hamstring muscles and muscles of the calf. Atrophy of the thigh and calf muscles is an early and reliable sign. The circumference of the thigh and calf should be compared with the other side.

Determination of pain producing motions. When the patient lies flat on the table the sciatic nerve pursues an almost straight course from its lumbosacral origin to the internal malleolus, underneath which it turns forward to pass to the toes as the plantar nerve. It has been demonstrated on the cadaver (5) that the painful motions in sciatic neuritis are those which produce tension on the nerve roots by stretching the sciatic nerve trunk.

When the patient is on his back, the examiner flexes the left leg at the hip (Fig. 7). Pain is elicited which may be referred anywhere along the course of the nerve. Pull on the nerve by this motion is due to angulation of the nerve at the hip. The main stress is due to pull on the nerve from below the point of this angulation. The mechanics of the main stress is analogous to the mechanics of pull on the hamstring muscles by this motion. On flexion the leg revolves about a center (the acetabulum) which is anterior to the center of motion of the sciatic nerve. The tension on the nerve is immediately and almost completely relieved by flexion of the knee joint. On passive flexion of the thigh, with the knee

bent little or no pain is elicited because the slack of the nerve by knee flexion is usually more than sufficient to compensate for the pull of the angulation at the hip joint. On passive flexion of the right (unaffected) leg no pain is elicited.

Again passively flexing the left leg to the point at which pain is first elicited because the inner dorsiflexes the ankle joint. Acute pain is produced in the course of the sciatic nerve. Dorsiflexion of the ankle joint can have no effect on any of the tissues of the lower trunk except the sciatic nerve. The angle which the nerve turns below the malleolus is increased on dorsiflexion of the ankle joint, thus causing a pull on the nerve trunk. Pain on this motion is one of the few signs which is characteristic of a single lower trunk injury. It was first described by Roussy.

When the straight leg is flexed at the hip abduction and inward rotation relieve the tension on the sciatic nerve because in this position the nerve course is more nearly a straight line. With abduction and inward rotation there is greater range of motion without pain is possible. Adduction and outward rotation have the opposite effect. Flexion of the trunk is painful. That part of the flexion due to motion of the lumbar spine is free but forward rotation of the pelvis elicits pain in sciatic neuritis as the effect on the sciatic nerve is exactly the same as in passive flexion of the straight leg. In sitting, trunk flexion elicits little pain; this motion is comparable to flexion of the thigh with the knee bent.

The posture described under inspection is the position which causes the least pull on the nerve roots—namely eversion at the hip, flexion at the knee, and extension at the ankle joint.

Other physical signs. Physical signs characteristic of nerve lesions may be found such as absent tendo-achilli reflex, anesthesia may be present. Because they so clearly indicate a nerve lesion as distinguished from lesions of other tissues involved in lower trunk injuries, they are of great importance and are never present. In some cases they are transient or are never present. In other cases they persist long after

the pain and disability have disappeared. The pain on specific motion is more reliable than other signs as an index of the disability caused by neuritis.

Hamstring muscle spasm and sciatic neuritis. Hamstring neuritis in the acute stage is often associated with hamstring muscle spasm. The motions painful in the two conditions have many similarities, and the pain in both conditions is referred to the dorsum of the thigh. But hamstring spasm may be due to sacro-iliac and occasionally to lumbar spasm. The spastic muscles always should be palpated before a diagnosis is made. The pain on dorsiflexion of the ankle joint sometimes present in neuritis is a valuable sign. It is never found if the hamstring spasm is due to any lesion other than neuritis. Tenderness of the trunk of the nerve is helpful, but not often found. Most important is the search for signs of the other lesions producing hamstring spasm. The commonest mistake in the diagnosis of lower trunk injuries is to diagnose as sciatic neuritis the hamstring spasm due to sacro-iliac or lumbar strain.

Malingering and exaggeration. Backache is a frequent complaint in compensation cases, and in view of the financial benefits involved, the possibility of malingering must always be considered. A distinction must be made between malingering and exaggeration. When a patient has a long continued back pain and has been told by several physicians—"nothing to be seen, the ache will pass off"—it is not surprising that he grows apprehensive and exaggerates his symptoms when the pain persists. If the physician knows the physical signs it is not difficult to find inconsistencies which are the hall-mark of malingering. There is no single sign which proves malingering; it is the inconsistency of the signs on which that diagnosis is based.

A patient may allege inability to flex the trunk more than a few degrees on standing. When on his back it is found that thigh flexion and pelvis rotation are normal. The findings in the two positions are inconsistent. Even though he had a poker spine he could bend the trunk to a fair extent with normal motion at the hips. He is definitely malingering.

When a patient alleges more marked restriction

tion and pain on flexion of the thigh with knee bent, than in straight leg raising, we know we are dealing with malingering.

I have seen the following signs erroneously described as signs of malingering.

1. With the patient prone on the table, he alleges pain on flexion of the knee. Comment: the flexion of the knee in this position by pull on the rectus femoris, produces a forward rotation of the pelvis. It may therefore, produce pain in the sacro-iliac or lumbar sprain but never in sciatic neuritis or ischio-gluteal bursitis.

2. A patient who keeps his lumbar spine rigid in flexion of the trunk is placed supine on the table on dorsiflexion of the two thighs simultaneously it is found that the lumbar curve can be changed without pain. Comment: when the pain is due to strain on a muscle which has latent spasticity the pain may be present in active flexion of the trunk when standing, and absent with passive motion of the spine when lying down. Sir John Collie describes this as a sign of malingering. It is occasionally found with lumbar muscle spasm and is then no indication of malingering. Failure to flex the spine is not the same as failure to flex the trunk.

3. The presence of exquisite superficial tenderness. Comment: the fact is that exquisite superficial tenderness may be present in the area of any spastic muscle.

SUMMARY

1. Each lower trunk lesion produces pain in a definite combination of motions which is characteristic of that lesion. Supposedly pathognomonic signs are misleading.

2. The physiological principles which account for the elicitation of pain by specific test motions have been described.

3. Each lesion may produce spasm in certain muscles and does not produce spasm of other muscles.

4. The various signs bear definite relationship to one another. By inconsistencies

in these relationships, the diagnosis of malingering can be made.

THE ENERGY BACKGROUND OF THE GENESIS OF GALL STONES AND OF THE PREVENTION OF IMMEDIATE POSTOPERATIVE SHOCK AND OF LATER DIGESTIVE DISTURBANCES¹

GEORGE CRILE, M.D., F.A.C.S. CLEVELAND, OHIO
Cleveland Clinic

THE conceptions of classical physics were profoundly altered by the researches which followed the discovery of the X-ray. The conceptions of classical physics and biology are now undergoing a profound alteration as the result of researches into the radiant and electric energy of protoplasm.

In Europe following the work of Gurwitsch and others, these new conceptions regarding the rôle of electricity and radiation in the activities of protoplasm have advanced so far that the International Society of Electroradiobiology has been formed with an official journal *Radiobiologie* the first number of which appeared in April 1932.

If we are correct in our assumption—and this assumption is based on experimental evidence—that the organisms of animals and of man are operated by radiant and electric energy and that a mechanism has been set up to render this energy available for adaptive purposes, then on this basis we should expect variations in the relative sizes of the energy units of this mechanism—the brain, thyroid and adrenal sympathetic system according to the adaptive needs of the species, and according to the varying demands of different age periods.

One of the characteristics which separates man from the other mammalia is his incessant activity especially mental and emotional. Wild and domestic animals secure food, procreate play and sleep. Primitive or uncivilized man is relatively inactive. Civilized man however works all day and worries at night. The level of energy expenditure is one of the measures by which we may estimate the level of civilization. Therefore, one would draw the inference that the evolution of man involved the brain and also the gland that governs the rate of metabolism namely the thyroid gland.

With a normal thyroid there is normal brain activity. With a deficient thyroid there is diminished brain activity. With excessive thyroid activity there is excessive brain activity. The thyroid hormone maintains the level of activity of the brain. One would therefore expect the relative sizes of the thyroid, the adrenal sympathetic system, and the brain to vary with the energy characteristics of animals that is, one would expect that the size of the thyroid would increase in proportion to the rate and constancy of demands for energy production while the size and intricacy of the adrenal sympathetic system, on the other hand, would vary with the need for sudden use of that energy (Fig. 1). It would follow that the size of the thyroid in relation to body weight would be greater in man than in other mammals, and that the adrenal glands, as Cannon has shown, being the organs that govern the outbursts of energy would be larger in relation to body weight in the animals that depend on a rushing attack or a swift escape.

Moreover, one would suppose that the nerves and ganglia which are associated with the adrenals would be much more abundant and their arrangement more complicated in animals in the energy group such as the tiger than in animals in the protected group such as the alligator.

Studies in the comparative anatomy of the brain, thyroid and adrenal sympathetic system have shown that these assumptions are well founded in particular as regards the intricacy and size of the adrenal sympathetic system which is large and complicated in lion and tiger (Fig. 2) less so in man whose frontal lobe, however, is most highly developed (Fig. 3) while both the brain and the adrenal sympathetic system are small and uncomplicated in the crocodile and in the alligator (Fig. 4).

(Fig. 4)

¹Presented at the Temple University School of Medicine (on the occasion of the symposium of a portrait of Dr. W. W. Keen in the School by the third and fourth year classes), Philadelphia, Pennsylvania, May 8, 1934.

If the brain, the thyroid gland and the adrenal sympathetic system are thus linked together it would follow that in a state of abnormal activity or what we may term pathological physiology of this great system the whole organism would be affected, with the resultant production in one individual of hyperthyroidism, in another of diabetes in another of peptic ulcer in another of gall stones. None of these originates within the affected organ. The thyroid gland does not originate hyperplasia, hyperplasia is imposed upon the thyroid gland. The stomach does not originate a peptic ulcer the condition within the stomach which produces an ulcer is imposed upon the stomach by influences outside itself. The pancreas does not originate diabetes, diabetes is imposed upon the pancreas and so it is with gall stones: their origin is not within the gall bladder nor within the liver but the condition which produces gall stones is imposed upon the liver by influences outside itself.

That emotion physical exertion—any excess transformation of energy—affects the whole energy system is well known as has been shown by Cannon and ourselves. That such hyperactivity of the adrenal sympathetic system affects the liver has been demonstrated by our histological and biophysical researches.

Twenty four years ago we conducted an extensive histological research to discover what organs and tissues are affected by excess or diminished transformation of energy in the body. In this research a histological examination was made of every organ and tissue in animals which had been subjected to insomnia to fear to physical injury to shock to prolonged anaesthesia to infection. In every case histological changes were observed in three organs and in three organs only the brain the liver and the adrenals. The liver cells lost their differential stainability—they became swollen and oedematous the cytoplasm was vacuolated the nuclei were crenated and the cell membranes were irregular the most marked changes occurring in the cells nearest the periphery of the lobules (Fig. 5). Identical changes were found in the liver cells of patients who had died from infection puerperal eclampsia hyperthyroidism or in any

Fig. 1. Comparative sizes of the thyroid and adrenal glands (charted from actual weights)

case in which exhaustion was due to the protraction or intensity of the disease. Later biophysical researches disclosed that, under identical conditions changes took place in the temperature and in the electric conductivity, electric capacity and electric potential of the liver. These experimental facts confirm the clinical deduction that the change in the bile which leads to gall stones is not due to changes in the gall bladder but to changes in the function of the liver cells.

It would follow that one would expect to find the highest incidence of gall stones among races and individuals in whom the energy system is peculiarly active. How is this assumption borne out by known facts regarding the incidence of gall stones? Gall stones are rarely seen in wild animals in which although adequate for attack and defense the adrenal sympathetic system is not subject to prolonged stresses and strains. Dr. Herbert Fox, Pathologist at the Philadelphia Zoological Gardens has reported the finding of gall stones in but 14 of 5,365 autopsies on wild animals in captivity. Gall stones are less common in the lower races of man than in civilized races and

SURGERY GYNECOLOGY AND OBSTETRICS

among civilized races gall stones are less common among peoples who have a negative philosophy. Gall stones are most commonly found in Americans and Europeans less commonly in Asiatics. While gall stone disease is relatively common among Americans and Europeans it is most common among people of the Hebrew and Latin races.

In other words, gall stones occur most frequently in the active aggressive section of the human family, their incidence corresponding roughly to the distribution of hyperthyroidism, peptic ulcer, neurocirculatory asthenia, diabetes, highly emotional temperaments and high scholastic high executive and administrative ability.

Another significant fact is that among humans the incidence of gall stones is higher among females than among males especially among women who have given birth to children.

In pregnancy there is increased metabolism with hypertrophy of the thyroid and of the adrenal glands, there is a gain in weight, nervousness and palpitation are present, the organism is stepped up as in the expression of the emotions, in defense against infection, excessive and fatigue-producing work. Dr. E. L. Walsh, George W. Belcher Research Fellow of the Cleveland Clinic Foundation states that hypercholesterinemia is present in pregnancy. Therefore, since the liver cells are the only source of the bile in pregnancy, are the only source of the bile as in pregnancy, interfered with so profoundly as in pregnancy, the concentration of the bile is changed, and therefore the formation of gall stones is facilitated. But pregnancy itself is not the only reason why a married woman with children is more commonly affected by gall stones than men or non-childbearing women. The married woman has the children and the household and a husband on her hands as well. She is peculiarly subject to restraints and worries and anxieties and emotional strains all of which involve the adrenal sympathetic system and in consequence as we have demonstrated disturb the function of the cells of the liver. To that extent the childbearing woman is more prone to have gall stones than is her husband or the woman who has borne no children.

Any theory that is proposed to account for gall stones must account for all these facts. Our thesis is that the chemical and physical basis of gall stones is laid by changes in the secretion of the biologically active liver cells and not by changes in the sac that holds and concentrates the bile and performs no other function.

Let us consider the means by which the bile carries in solution such large quantities of cholesterol and bile pigment without forming gall stones in every human gall bladder. Dr. A. C. Ivy and Dr. E. L. Walsh and others have demonstrated clearly by their studies of the effect upon human gall stones of placing them in the gall bladder of a dog, and by experiments on the solution of gall stones in vitro, that the outstanding factors that govern the maintenance of the cholesterol and pigment in the gall bladder and ducts are the bile salts and the fatty acids. We may conclude that when these are present in sufficient concentration there apparently will be no formation of gall stones. Therefore when gall stones form they form because there is an insufficient concentration of bile salts and fatty acids or perhaps an excess of cholesterol. We know that in highly developed, high-strung emotional active people and in children bearing women the adrenal sympathetic system is hyperactive. We know that hyperactivity of the adrenal sympathetic system profoundly affects the cells of the liver. We know that when the liver cells are so altered, they will not secrete a normal quantity of bile salts and fatty acids.

A significant fact is that comparatively few of the individuals—animal or human—that have gall stones also have cholecystitis or gall stone colic. Since to per cent of the inhabitants of Europe and America have gall stones, there should be approximately twelve millions of gall bladders which contain gall stones in the American population at this time yet the total number of operations for gall stones and the total number of cases of gall-stone colic are relatively small.

We must offer evidence, therefore, that gall stones are not produced primarily by infection of the gall bladder as is the common belief. If in a hundred thousand cases, gall

Fig. 2 The adrenal-sympathetic system of the tiger

stones were taken from the gall bladder and replaced by any other foreign body of the same size and weight one might expect the incidence of infection and abscess to be approximately the same as in the case of gall stones in nature. In either case the infection might be due to the local irritation from the foreign body or from the gall stones. The question raised is whether the infection is not the *result* rather than the *cause* of gall stones. That this is the case is attested by the fact that there are at this moment in the United States, approximately twelve million people who have gall stones in their gall bladders and do not know it. Moreover and this is an even more important fact relatively few patients have an infected gall bladder or an abscess in the gall bladder without gall stones.

It is readily to be seen that when there is an interference by gall stones or infection with the free flow of bile in and out of the gall bladder there results an immediate interference with the concentration of the bile salts and fatty acids and to that extent the further formation of gall stones is promoted by the diminished concentration of the solvent bile salts and fatty acids. Thus an infection of the gall bladder by interfering with the concentration of the bile would

Fig. 3 The adrenal-sympathetic system of man

probably promote the formation of gall stones. We believe however that local infection is more commonly secondary just as in many cases of hyperthyroidism of peptic ulcer of Raynaud's disease of intestinal obstruction there are many secondary effects which arise from the primary cause. Therefore we may think of an infection of the gall bladder as being a complication of stones rather than of stones being a complication of the infection.

In this connection it is pertinent to recall that there was a time following the work of Halsted when it was believed by many pathologists and surgeons that gall stones were commonly due to the presence of typhoid bacilli in the gall bladder. It is now about 30 years since typhoid fever has been practically eliminated as a disease and therefore if this

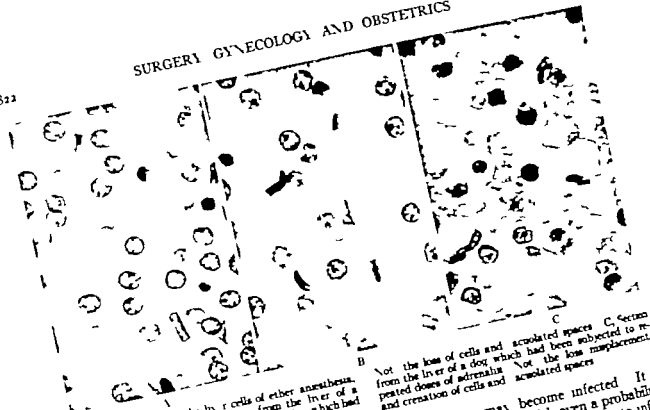

FIG. 8. Effect upon the liver cells of ether anesthesia. B and of adrenalin. C. Sections from the liver of a normal dog. B, section from the liver of a dog which had been subjected to continuous ether anesthesia for 4 hours.

Not the loss of cells and acellular spaces. C, section from the liver of a dog which had been subjected to repeated doses of adrenalin. Not the loss of cells and acellular spaces.

assumption were true the incidence of gall stones should be reduced by about 50 per cent. This is definitely not true—typhoid has disappeared, gall stones have remained. If gall stones are produced by the pyogenic infections, the greatest incidence of gall stones should occur in early life in the age of the highest incidence of infectious diseases in the period of the highest incidence of appendicitis of tonsillitis of tuberculosis, of osteomyelitis. These infections occur early in life—gall stones later.

Finally if it were a fact that infections have an affinity for the gall bladder then acute gall bladder infection should be as common as tonsillitis for the liver absorbs every kind of toxin and bacteria from the intestine. The it does not commonly become infected. The duodenum the stomach and the intestines are far more exposed to contamination than the gall bladder and ducts but they are rarely infected because they have a natural resistance. The gall bladder and ducts have a natural resistance and they too rarely have an acute infection except in the presence of stones which irritate them. If the stomach and duodenum are likewise irritated or dam-

aged they too may become infected. It is indeed difficult to establish even a probability that the genesis of gall stones is due to infection except so far as the infection may have altered the liver cells.

We may conclude therefore that gall stones are due to an often repeated or continuous interference with the quantity and quality of the secretion of the liver cells, which results in a deficiency of bile salts and fatty acids, and therefore produces an abnormal quality of bile.

We can see, therefore, why the more emotional the individual or the race the more common the gall stones how excessive fatigue or prolonged or repeated infections or pregnancy may predispose an individual to the formation of gall stones. Why the Jews and the Latins show a higher incidence of gall stones than do such races as the Hindus with the Nordics or the Chinese and the Hindus with their peculiar diet and negative philosophies of Confucianism or Brahmanism, or any human beings who have rationalized their lives and freed them from their stresses. What is there to change the liver cells in the primitive man who needs only to pluck an orange

or dig up a root, and then can sleep and loaf the rest of the day?

It is the adrenal sympathetic system acting upon the liver not the gall bladder and bile ducts which provides the fundamental cause of gall stones. It is not local infection not pathological morphology but pathological physiology which lays the background for the formation of gall stones.

We have an additional line of very definite evidence to offer. Dr Walsh has stated that in an experimental animal in which a biliary fistula has been produced in the presence of infection, the bile is not secreted in the usual amount and in normal concentration until several days after the animal has been subjected to a surgical operation and that any laboratory animal that is in ill health shows a diminution of the amount of bile secreted and in its concentration.

If there is any one fact that the experienced surgeon knows clearly regarding the sequence after operation on the gall bladder it is that a great change takes place in the quality and the quantity of the bile as the result of the surgical operation. At the present time when surgeons are commonly removing the gall bladder there is little opportunity for observing the flow of bile as in former periods when we removed the stones and drained the gall bladder. Then there was a perfect opportunity to note the effect that the anæsthetic the shock infection etc. had upon the quality and the flow of bile in other words upon the function of the liver cells. Every surgeon who remembers those days or who at the present time has observed the character of the bile in serious cases as in cases of jaundice in which the gall bladder is drained has noted that the liver cells were not able to secrete bile for a period of time perhaps not until 24, 48 or even 72 hours after the operation and he will remember his relief when normal bile again began to flow.

Every surgeon probably has performed apparently successful operations on the biliary passages of patients whose liver function was depressed. At the close of the operation the prognosis would seem promising but the following postoperative picture would soon begin to develop. The patient would become increas-

ingly apathetic his energy would be slowly depleted, though tired and weak he would not be able to sleep, the tongue would become increasingly dry, the pulse would gradually rise and its volume steadily decrease, the bile would be suppressed, nourishment would be refused, the patient's demeanor would be cheerless and despondent. The patient would seem to be sinking steadily in the quicksand of some fundamental failure of normal metabolism. No means would suffice to change the course of events. The patient would either recover gradually or else would become first delirious and then unconscious until death.

This is a familiar picture after operations on patients exhausted by chronic empyema of the gall bladder or by long continued infections from common duct stones. It is a familiar picture after operations on patients exhausted by prolonged or by sudden intense psychic strain or by some severe chronic infection. The temperature and pulse of these patients may be normal and if the prognosis were based on these factors alone the greatest errors would be made.

We now know that this picture was due to the effect of the surgical trauma the anæsthetic, and the psychic influences which attended the operation. All of these affect the adrenal sympathetic system and through the sympathetic system profoundly affect the liver cells.

It has been established by laboratory experimentation that the liver performs its function in part through direct nerve stimulation over the sympathetic system and in part through hormone action. The nerve supply of the liver is derived from the sympathetic and parasympathetic systems. These nerve fibers pass along the blood vessels and the common duct. In addition to the nerve supply to the liver as a whole each separate liver cell has its own nerve supply, not only is its outer border supplied but a filament of nerve tissue penetrates each separate cell (Fig. 6). One would expect to find that an organ every unit of whose structure is thus wired would have a close relationship with the great functions of the body.

Anyone who has operated upon the thyroid gland will remember that even an approach

The Johns Hopkins Hospital Reports, Vol. IV, p. 331.

to the recurrent nerve—merely touching it or producing the slightest traction on it—causes at once a great change in the conductivity of that nerve which is expressed by a change in the voice. The reason is that this nerve is poorly protected as are all nerves which being deep-seated have always been phylogenetically protected from injury. If it were possible for injury of the liver cells to be demonstrated by arising out as is injury of the laryngeal nerve the demonstration would be dramatic indeed.

Since as our experimental researches have shown physical trauma and inhalation anaesthesia affect the liver cells, it is obvious that for the protection of liver function minimum trauma must be inflicted and that the minimum degree necessary to secure the required relaxation, principal dependence being placed upon local, regional, and splanchnic anaesthesia.

After leaving the hospital many patients complain of a group of distressing symptoms

(1) lack of vigor and endurance (2) pains (3) indigestion. These symptoms may continue for many months—even for a year or more. It would seem that their genesis may now be explained and these sequelae prevented because as we believe the symptoms are due to injury of the sympathetic nerves which are so richly supplied in the precise area of the operative attack. These nerves are as delicate as the spinal cord. What if the neurosurgeon should pack the brain, the medulla the spinal cord to stop bleeding or retract them with force to make up for the relaxation a proper anaesthetic would give. Not only does the surgeon cause a profound interference with the innervation of the liver but also with the whole adrenal sympathetic system—with the innervation of the pancreas, the adrenal glands, the entire gastro-intestinal tract. In addition to such injury this sensitive exquisitely delicate telephone switchboard of the sympathetic system is harmed enough to cause scar tissue to form then this system will cause the above mentioned symp-

toms to continue for months or years just as in the case of injury of the recurrent nerve in a roughly conducted thyroidectomy with the formation of scar tissue

The indigestion and lassitude following operations on the gall bladder and ducts is the surgeon's disease. With this conception in mind I so plan and execute the operation that the network of the sympathetic is only slightly disturbed and as a result these distressing postoperative symptoms are no more than those which follow a pelvic operation.

From these considerations it would appear that the genesis of gall stones and the prevention of postoperative shock and of later digestive disturbances are related to the energy system which is the mechanism through which the radiant and electric energy operating the organism is principally expressed.

SUMMARY

1. A transformation in regard to our conceptions of the energy whereby living organisms are operated is now in progress and will inevitably affect biology and medicine.

2. There is nothing more definitely established than the fact that the injection of

adrenalin, the expression of an emotion, foreign proteins, an infection, a great exertion, a physical injury, pregnancy, all produce an increased activity of the energy system of the organism, and the liver is linked indissolubly with that energy system. In other words, all the factors that cause an increased output of adrenalin in the experimental laboratory have the power of changing or modifying or interfering with the cells of the liver and in consequence with their production of normal bile.

3. This change in the liver cells is the result of hyperactivity of the adrenal sympathetic system.

4. Change in the cells of the liver in turn predetermines a change in the bile content, change in the bile content, as shown by the researches cited, leads to the formation of gall stones.

5. Immediate shock and postoperative indigestion and pain are almost completely prevented by avoiding injury of the exquisitely sensitive sympathetic nerves by avoiding the formation of scar tissue which involves the rich and intricate network of the sympathetic nervous system.

Total Abdominal Hysterectomy—Lillian K. P. Farrer

CLINICAL SURGERY

FROM THE CLINIC OF THE WOMAN'S HOSPITAL NEW YORK

TOTAL ABDOMINAL HYSTERECTOMY

ANATOMY AND TECHNIQUE¹

LILIAN K P FARRAR, A B M D F.A.C.S. NEW YORK NEW YORK

THE operation of hysterectomy has been a matter of evolution over a period of approximately 50 years. Probably the greatest impetus and contribution to the technique was given by Dr Lewis A. Stimson, a founder and the first professor of surgery in Cornell University Medical College. On January 9, 1889, Dr Stimson described before the New York Surgical Society the technique of two total abdominal hysterectomies which he had just performed. In these two operations Dr Stimson had applied ligatures to the uterine arteries alone underneath the peritoneum with the object of preventing first, hemorrhage from the retraction of the blood vessels; second, the sloughing of the pedicle. In this meeting Dr Stimson asked the opinion of his fellow members of the relative value of total or subtotal hysterectomy, saying that he himself believed the total to be the better procedure. In July of that year Dr Stimson published his paper entitled "On Some Modifications in the Technique of Abdominal Surgery, Limiting the Use of the Ligature *en Masse*", and stated that if the cervix was left *in situ* it should be covered with a flap of peritoneum thus solving the problem of the treatment of the pedicle or stump which had so long been a stumbling block in hysterectomy. The value of this and the isolation before ligation of the uterine artery was quickly recognized. These two procedures have revolutionized the operation of supravaginal hysterectomy—but total hysterectomy which Dr Stimson advocated has not been at least in this country generally accepted for benign condition of the uterus.

The ease with which the supravaginal method may be carried out and the brilliant work of the leaders of the next decade have led to its great popularity in the United States—so much so that in Europe today the supravaginal hysterectomy is called the American operation. In France Doyen, Wurt and Fergue and in Germany and Austria Bumm, Doederlein and Weibel and be-

fore the latter Wertheim, have all advocated the total operation for non-malignant conditions necessitating hysterectomy. In England Mr Herbert Spencer has for years practiced total hysterectomy for benign conditions of the uterus and has published statistics for all of his cases. The wisdom of this routine practice lies in the knowledge that cancer is not infrequently associated with fibroids of the fundus and that cancer of the cervix has been reported by numerous surgeons to have developed later in the cervical stump. The incidence of cancer occurring with fibroids is probably about 5 to 8 per cent. Munro-Kerr found in his cases 5 per cent malignancy in 200 fibroid tumors of the uterus and quotes Ellice McDonald as finding 5 per cent malignancy in 700 myomata uteri. Polak studied 900 fibroids and found cancer undiagnosed and present in 2 per cent. The difficulty of curetting out all tissue from a uterine cavity distorted by myomata might be a reason for not diagnosing even a suspected case of malignancy and a second reason is that sarcoma rarely begins in the endometrium. An additional reason for the removal of the cervix together with the fundus was first given in 1896 by Chrobak, of the University Clinic of Vienna who reported 3 cases of cancer that had developed in the stump of a cervix several years after supravaginal hysterectomy had been done. In 1910 Dr John Osborn Polak collected from American literature alone 256 cases of carcinoma occurring in the cervix one year or longer after a supravaginal hysterectomy had been done and from all literature 900 cases of carcinoma occurring in the cervix thus left—Mason reported 29 cases of carcinoma in the cervix after supravaginal hysterectomy seen in 5 years at the Mayo clinic.

In the Woman's Hospital the incidence of carcinoma developing in the cervical stump one or more years after a supravaginal hysterectomy is 7 per cent of all patients who come to the clinic for treatment of carcinoma of the cervix. Spencer

¹Read before the American Gynecological Society in White Sulphur Springs, Virginia, May 1912.

quotes Peham and Amresch that carcinoma is 27 times more frequent in the cervical stump than in the cervix of women who have not had a subtotal hysterectomy. If this be so it is not probable that we are making tissue favorable to the development of cancer when we leave a cervix in doing a hysterectomy. Tissue that has been devitalized by any means such as by burning cauterization cutting off the blood supply makes that tissue more liable to become infected.

Leucorrhoea is a frequent symptom after supra vaginal hysterectomy in women who have never had a vaginal discharge before. Leucorrhoea results from the degenerative changes that follow in the mucous glands of the cervix. A chronically diseased cervix stimulates tissue reaction and cell proliferation and thus paves the way to the development of cancer. Leucorrhoea and backache are such common symptoms after the subtotal operation that many surgeons come out the cervical canal from above at the time of the amputation of the fundus or cauterize the cervical canal from below immediately preceding the abdominal part of the operation. This latter treatment however may be a source of severe infection as the slough lies so close to the abdominal wall. The coning out of the cervical tissue may or may not cure the leucorrhoea and may prevent the development of cancer depending upon how thoroughly the base of the glands are destroyed. But Peterson has shown that only one-third of the carcinoma of the

cervix begins in the cervical canal while two-thirds are of epithelial origin and begun in the portio of the cervix which is not destroyed by the coning out or cauterization of the canal. Years ago Doederlein was asked what he considered the best treatment of the cervix to be. He replied: "Die beste Stumpfbehandlung der Zervix ist eben deren ganzliche Wegnahme." This seems to be true today for as Dr. W. J. Mayo has written: "We must look upon local lesions as an invitation to cancer without regard to just what the actual cause of cancer may be. Leaving the cervix leaves an average cancer liability. And again Dr. Mayo says: 'I believe that total hysterectomy is a wise procedure if it can be done safely and usually it can.'"

The value of the total hysterectomy and the development of a simple technique was shown in 1917 by Dr. F. F. Baldwin of Columbus, Ohio. Dr. Baldwin wrote: "It entirely removes the possibility of malignant changes in the retained cervix and more or less morbidity from inflammatory or degenerative changes which may be present or which may occur in the part that is left behind. A year or two later Polak of New York published his technique demonstrating particularly the removal of the cervix. Worrell of New Zealand at this time presented his method of leaving a strip of the lateral walls of the ligaments and thus disturb the insertions of the ligaments on cutting out prevent prolapse. Lahey has much the same technique with especial guidance on this strip of uterus the cervix. Obviously though this in the fundus should not be left if cancer is present in the fundus and not infrequently cancer may be present and not diagnosed. Kennedy of the Woman's Hospital utilizes the cervical ligaments to prevent prolapse as in the vaginal hysterectomy. Richardson of Baltimore, in 1929 presented an admirably planned technique with the attention directed especially to the prevention of hemorrhage.

The higher mortality in the total hysterectomy is a deterrent to many surgeons. It may be due in part then to consider the mortality of Diamond operations. A fair statement is that of Diamond of the Hôtel Labrousse who says: "All our gynecs perform daily the subtotal, how many on the other hand have the same experience with the total?" Is it not true then that they reserve the total operation for the most seriously ill, the infected or those suspected of cancer of the fundus? *Il est donc artificiel et illogique de comparer des choses qui ne sont au fond pas comparables entre elles. Les membranes.* Certainly one cannot acquire the same skill in doing the less frequent operation as in the operation which one performs

daily. Polak has estimated that the mortality of subtotal hysterectomy should be not over 1.5 per cent and the total not over 2 per cent. While many may consider these figures too low and the ratio between the two operations to be too small one must bear in mind that the mortality rate for the subtotal operation certain figures must be added to tell the whole story. When a cervical stump that has an unsuspected carcinoma is left or when carcinoma develops in it later the subsequent mortality or morbidity should be added to the primary mortality of the subtotal operation. Radium treatment for carcinoma in the cervical stump is more difficult and more liable to be followed by a vesical fistula. Radium burns of the rectum are not unusual if a supravaginal hysterectomy has been previously performed and intestinal adhesions have resulted. Treatment of amputation of an infected cervix left after the subtotal operation should also count against the incomplete operation. It may however be of interest to view the statistics of individual operations and also the statistics of individual authors. Read and Bell give the figures shown in Table I for 14 surgeons. Nelson's figures are shown in Table II.

This makes 2,712 total hysterectomies done only by individuals but by the staffs of general hospitals with a mortality less than 2 per cent.

The criticism may be made that the statistics given are for the total hysterectomy as done by specially trained groups and not by the great number of surgeons doing gynecology as part of general surgery. For as Dr. John G. Clark wrote several years ago in his article on the abdominal operation for cancer of the cervix: "The universal benefit of any medical or surgical measure cannot be great if its execution is so difficult as to render it highly hazardous except in the hands of a very few specialists. It is with the desire to help simplify the operation of total hysterectomy that I

report this technique. The usual objections given to total hysterectomy are (1) more difficult technique (2) danger of hemorrhage (3) danger of injuries to bladder or ureters, (4) infection from the vagina, (5) shortening of the vagina, or prolapse of the vault of the vagina. It may be well to consider these objections first.

The technique. A consideration of the anatomy of the tissues involved may help to a better understanding of the technique in the pelvis, and the complexity of terms used by different writers has led to much confusion as to the purpose of these structures. The best description today of the pelvic anatomy is, I believe, that written by Dr. Julius Tandler, professor of anatomy in the University Clinic in Vienna. Briefly summarized it is as follows: "An analysis of the endopelvic fascia (called 'endo'—within—the pelvis simply to distinguish it from the fascia that is outside, lining the walls of the pelvis) shows that:

1. It is a true muscle fascia. The connective tissue takes its origin from the arcus tendineus on each side of the pelvis (Fig. 1) and extends to the mid pelvis to be inserted into the lateral walls of the uterus, cervix, and vagina. The underlying muscle is derived from the organs to which it is attached.

2. This endopelvic fascia covers over the pelvic organs, separating one organ from another and from the serosa which lies above or around each organ (Fig. 2). It sends down septa between the bladder and uterus known as the septum vesico-bladder and between the uterus and rectum, the septum recto-vaginale. (Fig. 3.)

3. In some places this endopelvic fascia is greatly strengthened and forms true ligaments but in other places it exists merely as an areola net work the interstices of which are supplied with fat to fill in the spaces between organs. From above the endopelvic fascia appears as a broad sheet of fascia anteriorly at the base of the bladder the muscle which is derived from the vagina and bladder it extends from the os pubis to the vagina and cervix as the ligamentum pubo-vesico-vaginale. Laterally on each side of the pelvis the endopelvic fascia is composed of thick bundles of connective tissue and smooth muscle and extends

from the pelvic wall to be inserted into the lateral walls of the uterus and cervix. Looking from above the endopelvic fascia (Fig 4) radiates like an open fan from the lateral wall of the uterus to the pelvis. In sagittal section it is three-cornered. The muscle is thickest at its insertion into the uterus but varies in amount, with the age and development of the individual. In pregnancy the muscle is greatly thickened and the blood supply increased to make a vascular muscle sling for the uterus. Later in life this muscle atrophies and the fat is absorbed. The nerves, lymphatics, and blood vessels supplying the uterus, cervix and upper vagina lie in its depths. The whole forms the so called parametrium. A variety of names have been given to this structure. It is known as the ligamentum transversum colli of Markenrodt, the ligamentum cardinale of Koch, the sustentaculum of Bonney, the upper pelvic floor of Polk, etc. (The anterior and posterior lamella of the peritoneum cover the parametrium, the fallopian tube and mesosalpinx and include the ligamentum ovarii proprium and mesovarium to form the broad ligament.) At the anterior edge of the parametrium the endopelvic fascia continues on each side of the pelvis as a thick bundle of connective tissue and smooth muscle to form the so called ligamentum teres. At the posterior edge of the parametrium on each side it forms in similar way the ligamentum sacro-uterinum which unites with its fellow from the other side to surround the rectum. Between these different ligaments are spaces filled with areolar connective tissue and fat. This whole sheet of endopelvic fascia when seen from above might be likened to a cartwheel, the spokes of which are the ligaments joined at a central point the hub or uterus. When the hub or uterus is cut away the spokes or ligaments, must be united at a new central point. This joining of ligaments ensures a long vagina without danger of prolapse.

2 and 3. *Hæmorrhage Bladder and ureters* The blood supply of the body of the uterus, the cervix and the upper vagina and bladder comes from the uterine artery which is derived on each side from the hypogastric artery. After the uterine artery has crossed the ureter and before it enters the uterus it gives off three or four branches. The branch nearest to the uterus (Fig 5) is the annular artery which unites with the artery on the opposite side to supply the cervix. The second branch is the anterior vaginal artery which supplies the upper vagina and the third branch is the vesical which goes to the posterior wall of the bladder. The uterine veins follow the course of the uterine arteries. The venous return is carried

Fig 6. Blood supply of the uterus after injection of the two uterine arteries. (From Deve, Thèses d. l. Fac. de méd. Paris)

up by the uterine veins to the hypogastric veins and on the right side to the inferior vena cava on the left usually to the left renal vein. In 1892 Dr William M. Polk demonstrated before the American Gynecological Society the anatomical arrangement of these vessels and advocated ligating the uterine artery median to the anterior vaginal branch. These arteries and the plexus of veins have been clearly shown by X ray after injection (Fig 6) of the blood vessels of the uterus. Faure and Wiart in France, Bonney in England, Richardson and Lahey in this country have stressed the importance of properly applied clamps to control the arterial bleeding and the venous oozing at the vaginal angles. Bonney says: "If the arteries have been properly isolated and the clamp has been applied at a point just distal to the origin of the vaginal branch the remainder of the operation is practically bloodless. If the bladder is pushed off the anterior surface of the uterus to its interureteric fold the ureters are sufficiently far below the uterine arteries to be out of danger of

Fig. The peritoneum in front of the right round ligament is nicked and blunt-tipped scissors are introduced to push the bladder back.

injury. When the uterus is pulled upward and obliquely backward the uterine artery lies at nearly a right angle to and now well above the ureter. It is usually possible to see the course of the uterine artery after it is located at the lateral wall of the uterus and to palpate it between thumb and forefinger before it is ligated just medial to the ureter. A ligature at this point shuts off the arterial blood supply to the uterus and bladder, and a second ligature on the uterine artery as it enters the uterus shuts off a little return. If the uterine artery is not visible a little gentle palpation or teasing of the tissues as Weibel does it, or if not successful the trick as Weibel terms it will locate it. A deeper palpation with the fingers at the posterior part of the parametrium close to the uterus, as described years ago by Stimson. To quote Bonney again: "No for-

ceps are needed in cutting through the cardinal ligament when this vessel is controlled." Considerable time is saved in operating by ligating the uterine artery at these two points. There is freedom from active bleeding and also from the continued venous oozing that is so troublesome. It eliminates too the placing of clamps deep in the pelvis in close proximity to the ureters at their entrance to the bladder.

Infection. The danger of infection from the vagina in performing total hysterectomy is, I believe, far less than the danger of infection in cutting across the cervix in the subtotal operation. There are no glands in the vault of the vagina, and therefore it is easier to disinfect this area than to render sterile a cervix that may harbor infection in the depths of its racemose glands, or to render sterile a sloughing growth in the cavity of the uterus that one may have to cut into in removing the body of the uterus. Read and Bell state that the deaths following subtotal hysterectomy and pulmonary embolism is the cause of one-third of only one-tenth of the deaths in total hysterectomy. Other writers place the mortality from embolism in subtotal hysterectomy as high as 50 per cent. A low grade infection is frequently the cause of thrombosis and embolism. The higher percentage of embolism in the subtotal operation may perhaps be due to infection from a diseased cervix or infection from the intra uterine cavity.

The thorough cleansing of the vault of the vagina

Fig. 8 Step 5

Fig. Step 6

Fig. 11 Step 8.

Fig. 12 Step 10

Fig. 13 Step 11

is a most important part of the preliminary preparation of the patient and should be done personally by the surgeon or at least supervised by him ally by the surgeon of vaginal tissues. The shortening or prolapse of the vagina following total hysterectomy is due to the improper suturing or not suturing of the ligaments which were inserted into the uterus. When the uterus is cut away these ligaments should be fastened to one another and to the cut edges of the vagina. This prevents either the shortening or the prolapse of the vagina.

THE OPERATION OF TOTAL ABDOMINAL HYSTERECTOMY

The investigation of a patient's condition before operation should include the usual examination of heart, lungs, and also the throat for infection, the routine urinalysis and a phenolphthalein test of the kidneys. The blood count should be not less than 3,500,000 red cells and 70 per cent hemoglobin or the operation should be postponed until a blood transfusion can be given. The white cells should be between 5,000 and 10,000. The blood pressure of normal average for the age of the patient. All cervical erosions must be healed before operation to prevent infection. The patient should be in the hospital at least 24 hours before the operation to care for the intestinal tract and prevent the farewell lunches or dinner parties that are not infrequently the cause of much postoperative trouble. A sedative the night before operation and a preliminary hypodermic of morphine and atropine helps to quiet the nerves for the operation. If the patient is elderly or a poor risk I have been in the habit of several years of having a solution of gum acacia and glucose given intravenously during the operation as a supportive measure, and at the closure of the abdominal incision to have given by rectum a quart and a half of saline solution, or what Dr. John Clark termed, an internal hot water bottle to offset the loss of body fluids.

Step 1. When the patient is under the anesthetic and in the lithotomy position after the external genitalia have been cleansed and the bladder catheterized, the entire vagina should be thoroughly scrubbed out with sterile gauze sponges on long sponge forceps. Especial care should be given to cleaning around the cervix at the vault of the vagina. A douche being used to reach to the vault of the vagina. A sterile weighted speculum double tenaculum, Denver vaginal retractor, cervical dilator, gloves, and long intra-uterine syringe will be needed. An ounce of 3%

per cent tincture of iodine is injected into the uterine cavity and the iodine withdrawn into the syringe at the external os so as to avoid any washing out of cancer cells. The cervix and vault of the vagina are painted thoroughly with fresh iodine. The external os is sutured and 3 yards of two-inch iodoform gauze is packed snugly into the vault and around the cervix. This packing helps lift the vault of the vagina when the cervix is cut out and remains *in situ* 48 hours after the operation as it keeps the tissues protected. There is no danger of sewing this gauze to the vaginal edge as there is so much elastic tissue in the vagina that it can be pulled up as soon as the cervix is cut out.

Step 2. After a median abdominal incision from the pubis to the umbilicus (or curved to right or left and then above if the abdominal wall is thick) the edges of the wound are protected with gauze. A self retaining retractor is inserted, the patient is placed in the Trendelenburg position, and the intestines are packed back (Three Bovie sell rubber pads or pockets filled with Turkish towelling are a decided help and do not sand paper the intestines as gauze packs do).

Step 3. An artery clamp is placed on each round ligament close to the uterus and the tissue pulled taut. The peritoneum just in front (Fig. 7) of the right round ligament is nicked and blunt tipped scissors are introduced to push the bladder back. The vesical peritoneum is cut after the bladder is pushed away and several Allis clamps are placed on the cut edge. The round ligaments are then cut across and each tied, the suture being left 2 or 3 inches long with a clamp on each so they are to be used in the closure of the vagina.

Step 4. A sharp toothed Kocher forceps is clamped on each side of the uterus. (No sharp toothed or elevating forceps should be applied to the fundus as cancer may be present and unsected.) A small artery forceps is passed directly under each fallopian tube and the tissues pushed downward to allow the ureters to drop farther away. The tubes and ovaries are then removed as they are deemed best, the ovarian arteries being ligated at the infundibulopelvic ligament or at the uterus. I always leave normal ovaries in the fundus, and thollogat reports no carcinoma in the fundus, and the tube with each ovary. If there is no appearance of infection in the tube, as there is less disturbance of the blood supply to an ovary if the corresponding tube is left. If the tubes are removed it is desirable to leave at least one ovary and if there is doubt as to its condition it may be placed just above the peritoneum when the abdominal wound

is closed I have done this several times and so far I have never had to remove the ovary, nor do I know of any trouble ever resulting from having left it. Each ovary and tube is ligated separately to avoid mass ligatures. If the tube is to be left I wipe out the lumen of the tube with small cotton wound applicators dipped in carbolic acid and the last one is dipped in alcohol. All blood vessels are ligated by sewing in the ligature to prevent slipping. The entire field is cleared of clamps before proceeding to the next step except the two Kochers on the uterus and the Allis clamps on the vesical peritoneum.

Step 5 The bladder is picked up with thumb and fingers and the vesical ligament is snipped with blunt tipped angle scissors, the incision being extended toward the uterus until the bladder is freed to the interureteric fold (Fig 8). When this fold is reached we know that the bladder is free to the trigone and that the ureters have dropped down in the pelvis. One can usually see the ureters entering the bladder and palpate each between the fingers as a flat cord,—and it is almost always possible except in the very fat patient, easily to trace the ureters through the parametrium.

Step 6 The uterine artery is located at its entrance into the lateral wall of the uterus. The uterus is pulled up and obliquely backward (Fig 9) and with thumb and forefinger the uterine artery is palpated for approximately three fourths of an inch from its insertion into the uterus. When certain that the blood vessels only are in the grasp of the fingers, while they are still held a needle with suture is carried directly under the vessels and tied at this spot which is *median to the ureter*, at right angles to it and now well above the ureter. I suture the uterine artery again just as it enters the uterus, and then suture the uterine artery to the fascia.

Step 7 Each uterosacral ligament is cut just above its insertion into the fascia and a Kocher clamp is placed on each ligament. The fascia is cut at this level entirely around the cervix, going approximately one fourth inch above the ligated uterine arteries. The parametrium is cut on one side to about one-half of its depth and then on the other side. The cutting is continued first on one side and then on the other until well down to the vagina. Usually when the parametrium is entirely cut through it is possible to pull the uterus up and out of the pelvis.

Step 8 To ascertain if the cervix is freed down to the vagina an incision is made between the uterosacral ligaments and the uterus is pushed forward to free it from the rectum (Fig 10). In a

similar way in front a finger is pushed down pressing back on the uterus to free it from the bladder (Fig 11). Test with a finger anteriorly and one posteriorly. If the lateral dissection has been continued downward sufficiently far the fingers will meet below the cervix.

Step 9 A bit of vaginal tissue is picked up between the uterosacral ligaments and nicked transversely. When the vagina is opened it is easy to push in a curved artery clamp fasten it on the vaginal tissue and cut the tissue close to the cervix. (I use a different clamp on the vaginal tissue from the one on the fascia simply to identify the edges of the vagina and work more quickly when suturing.) Repeat the procedure with clamp and cutting until near the bladder. Then the vaginal tissue is clamped and cut on the other side from posteriorly to the bladder. In this way the vaginal tissue near the bladder is left to the last when it will be easily seen and the bladder can be protected from injury. If one is in doubt how broad the cervix is and how far out to cut the vagina it is better to introduce a finger into the vagina rather than to put a hook into the cervix and draw it out as is often advised. When the cervix is entirely removed I apply iodine on a sponge to the vaginal edges and remove the excess iodine with a dry sponge. Up to the incision of the vagina the operative field will be almost bloodless if the ligatures have been properly applied. When the vagina is cut through there is some slight bleeding from the branches of the external vaginal arteries which supply the middle portion of the vagina and from the inferior haemorrhoidal artery but this is checked by the suturing of the vaginal edges.

Step 10 The edges of the cut vagina are closed with No. 2 plain catgut suture beginning on the right posteriorly, passing the suture from without into the vagina and out at the extreme right end of the tissues and returning into the vagina and then out at the anterior edge of the vagina (Fig 12). This secures the right side and I include at the same time a bite of the right round ligament and tie. A suture then from the posterior cut edge of the vagina to the anterior edge of the vagina closes the right half of the vaginal opening. In this suture I include again the round ligament, near its cut end. This firmly secures the vaginal tissues against prolapse. The steps are repeated on the left half of the vaginal opening.

Step 11 With the same type of suture the fascial edges are united, beginning posteriorly on the right by passing the suture from without through the fascial opening and out the extreme right end of the fascial tissue and back in this same tissue

and then out through the anterior edge of the fascia exactly as in the closure of the vagina (Fig. 13). Next a suture is passed from without through the right uterosacral ligament (included in this suture is the cut ends of tube and ovary if they have been left) and through the anterior edge of the fascia and tie. This procedure is repeated of the fascia and tie now only the peritoneal left side of the raw surfaces. There remains now only the raw surfaces. The

Step 12 There remains now only the peritoneum to be closed over the raw surfaces. This should be done carefully so that no raw edge is left for an adhesion to the intestine and possible debris later. A Lambert suture introduced one-eighth inch from the cut edge of the vesical peritoneum will roll in this edge and leave a smooth surface when the peritoneum is sutured down to the raw tissues.

Closure of the abdomen is the final step in the repair of the pelvic floor and is to be included in the hysterectomy if the patient is to warrant it.

This is the third year I have used this technique and so far there has been no haemorrhage, no injury to bladder or ureters, and no prolapse of tissues. It requires only a few minutes longer to perform than the subtotal operation but is well worth the time. The postoperative convalescence is decidedly better than after the subtotal hysterectomy. The mortality up to now has been 1.8 per cent.

SUMMARY

JOHN A. SIMMONS, a founder of an American school of gynaecology in Cornell University, has written a book in favour of the following

SUMMARY

SUMMARY

- (1) To Dr. Lewis A. Stimson, a founder of and the first professor of surgery in Cornell University Medical College belongs the credit for the following technique: (a) The locating of the uterine artery as it enters the uterus, and isolating of it before ligating when performing hysterectomy;
- (b) The covering of the pedicle or stump left in subtotal hysterectomy with a flap of peritoneum;
- (c) The recommendation of total hysterectomy which he performed in 1886;
- (d) The performance for total abdominal hysterectomy by the technique of the anatomy of the endometrium and the anatomy of the uterus.

3 This technique for total abdominal hysterectomy is based upon the anatomy of the endopelvic fascia and blood supply of the uterus, cervix, and vagina.

3 It lessens the danger of haemorrhage, pelvic fascia and vagina cervix, and to infection from junction to bladder or ureters, and to the uterine cavity passing across the cervix or into the vagina or pro-

3. It lessens the tendency of the uterus to bladder or into the rectum by cutting across the cervix or into the uterus.
4. It prevents shortening of the vagina.
5. It prevents the possibility of the use of the vaginal tissues after the operation.
6. It prevents the possibility of the use of the abdominal hysterectomy avoids the possibility of a diseased cervix or an unsound uterus.

5 Total abdominal hysterectomy
of leaving a diseased cervix or
in the cervix subtotal hysterectomy
blood sup-

5. Total abdominal hysterectomy with removal of ovaries and uterus, with the danger of leaving a diseased cervix.

ply and like all devitalized tissue is liable to infection. Many patients who did not have a discharge before the operation suffer later from an annoying leucorrhoea.

7 A devitalized cancer of the cervix. Many cases have a patient as cancer of the cervix. Many cases have a chronically diseased cervix. Many cases have a subtotal hysterectomy.

8. It is illogical to compare the mortality of the subtotal with the total hysterectomy as the conditions for which the two operations are performed are very different. Most surgeons perform distal supravaginal hysterectomy for fibromyoma of the uterus and do a total hysterectomy infrequently and usually only when it is known that the fundus is present.

9. For a fair comparison of the subtotal and total hysterectomies one must add to the primary mortality of the subtotal operation the subsequent morbidity or mortality of the removal of a diseased cervix, or radium treatment for a cervix that has developed cancer following hysterectomy. Total abdominal hysterectomy has been shown by many surgeons with a mortality rate of 1.5% to be a subtotal hysterectomy and not a total one. The design of the design

10 Total abdominal hysterectomy is performed by many surgeons with a low or lower than the subtotal hysterectomy should be the operation of choice for benign conditions of the uterus necessitating hysterectomy.

THE SURGERY OF GANGRENE OF THE EXTREMITIES

WITH A STUDY OF 171 CASES FROM THE RECORDS OF THE NEW ORLEANS CHARITY HOSPITAL¹
J. ROSS VEAL, B.S. M.D. AND ELIZABETH M. McFETRIDGE, M.A. NEW ORLEANS, LOUISIANA

MERLE Scott, Mont Reid and one or two other writers have repeatedly made the point that the field of arterial vascular disease has long been a neglected field and a badly handled field and Reid in a recent brilliant survey of the whole subject goes even further. Students and surgeons, he says, are no longer satisfied with efforts to classify gangrene and to determine the optimum level of circulation to stand they want to know the actual degree of circulatory embarrassment and to evaluate the rôles of the vasomotor nerves, mechanical obstruction, infection and the general condition of the patient. His attitude is both wise and hopeful for gangrene which is really an end-result as the initial manifestation of arterial obstruction and its management is still characterized by an attitude of utter hopelessness that does not promise well for the results of treatment. That there is some justification for despair it must be admitted. The patient with arterial obstruction must be saved from his disease before gangrene sets in if he is to be saved from death or from mutilation and that implies an entirely new conception of the condition on the part of the profession as well as of the laity. Reid and his associates at this time are voices crying in the wilderness, but they are also heralds of a new day.

On the other hand, however much one applauds their efforts and endeavors to emulate their methods the fact remains that the treatment of vascular disease of the extremities among intelligent private patients and its treatment, or rather the treatment of its terminal phenomenon gangrene, among ignorant public charges, are two very different matters. J. M. T. Furney, Sr. was quite correct when he remarked that anybody could amputate a leg but that it took a good surgeon to save a man. He did not however go all the way even the best of surgeons cannot save a leg that is beyond saving when it is first seen or that can be saved only by an unjustifiable risk of the time the public hospital the surgeon most of the has just one course open to him, prompt amputation for the reason that the patient most of the time presents himself too late to make conservation safe or practical. If he resorts to amputation without delay he may—though he does not

always—save the patient's life. If he practices watchful waiting hoping to avoid the mutilation that is abhorrent to all his instincts and training, he frequently falls in his attempt at salvage, and he always introduces the risk of an increased morbidity and mortality. The surgeon who procrastinates, no matter how worthy his motives may be, adds to the death rate in gangrene just as inevitably as does the patient who delays presenting himself for treatment or who refuses surgery when it is offered to him.

But there is another problem besides the major one of whether or not to amputate. Where to amputate is a very serious consideration. Some surgeons notably Eliason still observe the Heidenhain law that amputation is, as a rule best done high because at that level the presence of an adequate circulation is ensured. That there is ample ground for this position cannot be denied, at least in the absence of reliable tests to determine the constant observance of this rule is open to objection on two points. The first, and more immediately important, is that in all amputations the mortality rises in direct proportion to the nearness of amputation to the trunk, although the risk of secondary gangrene is naturally very much less. The second is that it is seldom possible to fit an artificial limb satisfactorily above the knee, because although a pressure-bearing stump can be obtained with little difficulty leverage to manipulate the leg is lacking. That point we do not believe as does Eliason can be ignored, particularly in these days, when more than ever before economic usefulness must be taken into consideration.

During the 5 year period ending in December 1933 there were 171 amputations of the extremities for primary vascular disease at the New Orleans Charity Hospital, of which 110 were for arteriosclerotic gangrene. 45 were for diabetic gangrene. 14 were for Buerger's disease and 1, both in cardinals were for embolic gangrene involving the popliteal artery. Sixty-seven of these patients died a mortality of 39.1 per cent, which though it is about the mortality reported from other clinics handling the same type of case is sufficiently high to demand earnest consideration, especially since preventive measures can elim-

¹From the Department of Surgery of the Louisiana State University School of Medicine.

nate much of it and can materially reduce the mutilating surgery which gives rise to it. We should be derelict, too even though we have attempted no follow up on these patients, if we did not emphasize a fact which Eliason called attention to in his most recent publication on this subject, that the immediate surgical and the deferred hospital death rates do not tell the whole story, to them must be added the proportion, the appalling proportion of patients who die within the year after their discharge and who cannot be ignored when the accounts are finally cast up.

The pathology of the various types of gangrene is so clearly understood today that only one or two practical considerations need be stressed here, the first of which is that whether the individual is suffering from arteriosclerosis *per se* or from arteriosclerosis associated with diabetes the fundamental pathology is precisely the same, its manifestations being different merely because in diabetes an additional metabolic factor is introduced. The essential sameness of these two types of gangrene was first pointed out by Buerger and by Eliason and Wright, and the correctness of their contention was immediately recognized. In both diseases the underlying pathological change is an obliterating endarteritis frequently associated with calcium deposits which affects all the vessels of the body from the thoracic aorta to the finest radicals. The narrowing of the lumen in the large vessels amounts, in the smaller vessels, to practical occlusion and leads in turn to alterations in the nutrition of the tissues especially of the kidneys, the brain the myocardium and the extremities, of which gangrene may be the end result.

The fact that the diabetic exhibits his sclerosis at an earlier age by approximately 10 years than does the essential arteriosclerotic, a difference which was first emphasized by Eliason and Wright, we shall discuss in more detail later. Here we would merely point out that the metabolic perversion of the diabetic counterbalances, if we may so express it, the enfeebled heart and kidneys of the older arteriosclerotic and that their surgical risk is from this standpoint, about the same. But the diabetic is peculiarly prone to infection, and when infection is once introduced insulin which is his sheet anchor at other times, loses a large part of its effectiveness and his risk is many times increased. The reaction of the arteriosclerotic to infection is more sluggish but it is by no means absent. It is present more often than is generally realized but it is a deep seated infection an underground process if we may so express it, that spreads along tissue planes and

that only rarely manifests itself by the line of demarcation for which traditionally the surgeon waits and because of the delay in the formation of which so many lives have been sacrificed. In both arteriosclerotic and diabetic gangrene, infection is always actually or potentially present. The arteriosclerotic may react to it more sluggishly, his gangrene may begin as the dry type, in contradistinction to the moist and always potentially infected gangrene of the diabetic, but in both diseases a vicious circle is likely to be established in which infection increases gangrene and gangrene increases infection.

The constitutional reaction in the diabetic is case for case, more marked than in the arteriosclerotic. The temperature rises the pulse is accelerated, and the increase in the blood sugar, the development of glycosuria, and the tendency to acidosis which result from the local condition are exceedingly difficult to control by routine or even extraordinary measures. In the arteriosclerotic the rise in temperature and in pulse rate is rarely marked in the early stages and is at any time a poor index of the amount of infection and toxemia present, as the surgeon who so regards it frequently finds to his cost. The added decade of life with all that it implies in the way of decreased function of the vital organs introduces an immediate added risk, and a clinical appreciation of the patient's general well being or more correctly, his lack of well being is a better guide to his condition than are the usual signs. In these patients toxemia is manifested by an indifference to food a markedly reduced fluid intake with a corresponding reduction in the fluid output, a listlessness and drowsiness that at times approach actual stupor and an involvement of the cerebral vessels manifested in many cases by a mild senile dementia. This picture we have been particularly impressed with in the patients in our colored male wards and the improvement in our results since we have realized its significance and have sought to correct it, especially by forced fluids before and after operation has been most gratifying.

Buerger's disease or thromboangitis obliterans which is a presenile inflammatory disease of the vascular system characterized by gangrene of the fingers and toes rather than by massive gangrene exhibits as a rule premonitory signs and symptoms which cause the patient such extreme discomfort that he usually presents himself for treatment long before frank gangrene impends. The possibility of gangrene in the diabetic is always present in the mind of a careful physician, provided that the diabetic has presented himself

for treatment which is not always the situation. Eliason reports that more than half the patients with diabetic gangrene in his series did not know they had diabetes and we found almost the same proportion in our own cases. The danger to the diabetic of minor trauma such as arises from perching calluses, cutting corns, wearing tight shoes or shoes with rough linings, or even stubbing the toe, has been repeatedly emphasized but we do not believe that the almost equal danger of such slight insults to the arteriosclerotic has been sufficiently stressed. Moreover it has only recently been realized that patients with arteriosclerosis frequently exhibit signs of their disease which if properly interpreted, can serve to prevent graver consequences. Reid more than any other writer has stressed the fact that intermittent claudication pain in the feet and legs which is aggravated by walking and is worse at night, numbness and coldness of the extremities, swelling, discoloration and similar signs and symptoms all demand prompt attention and treatment because they are all warnings of impending trouble.

We were particularly interested in this phase of the cases we studied. In 139 of the 171 cases it was possible to determine from the history the precipitating cause of the gangrene which proved to be trauma in 43 (of 91) cases of arteriosclerotic gangrene 28 (of 41) cases of diabetic gangrene and 2 (of 7) cases of Buerger's disease. That is, trauma of some sort precipitated the gangrene in 73 of 139 cases in which the history was adequate. Furthermore in more than half of the cases in the arteriosclerotic group the history showed that arterial disease had been present and could have been treated long before the gangrene made its appearance, for the signs and symptoms had not been noted again and again. Patients can not be treated of course who do not present themselves for treatment but at that, one looks with regret on the lost opportunities in this particular group of cases, on the fatalities that could have been averted, and on the radical surgery that had to be done because those opportunities were lost.

Lemann writing in 1927 on gangrene in the South, called attention to poor pedal hygiene as a very important cause, particularly among negroes, and we desire to stress that point again. Indeed we could scarcely avoid stressing it, for 107 of these 171 cases, 62.5 per cent occurred in negroes, as did 42 of the 67 deaths, 62.6 per cent. All the points that Lemann made 7 years ago still hold. Negroes wear cheap and badly made shoes, which are full of unevenness if not of actual holes, their socks if they wear socks,

are in like condition their feet are badly kept and seldom washed, and partly because of the color of their skin, partly because of their habitual uncleanliness, minor abrasions and injuries, even initial gangrene, are frequently overlooked. The negro's habit of smearing himself with salve for all local conditions is often at least a partial explanation of the infection which usually accompanies his gangrene while his habit of delay in treatment for even serious disease is too well known to need extended comment. It does seem obvious, however from what we have just said, that it is quite as important to advise the arteriosclerotic in the care of his feet as it is to advise the diabetic.

The difference between the white and negro incidence and mortality is so striking as we have just noted that it is unfortunate that no comparative figures are available. In our own series 80 cases of Buerger's disease as would be expected occurred in the negro, but 82 of the 110 cases of arteriosclerotic gangrene were in the race as were 25 of the 45 cases of diabetic gangrene. In Eliason's last report of 175 cases of diabetic gangrene the negro to white ratio was 1-4 but a comparison with our own statistics means nothing in view of the different racial proportions in the two cities, not to mention the fact that the negro of the South and the negro of the North are in all respects different. Lemann, writing in 1927 pointed out that in the preceding 6 year period 1 of every 5 negro diabetics applying for admission to the New Orleans Charity Hospital exhibited gangrene, the negro incidence of that complication being 21 per cent against the white incidence of 14 per cent. In our own figures, which cover the period from 1929 through 1933 we found the disproportion still existing though it was less striking. Forty of the 310 cases of diabetes in the negro were associated with gangrene 13 per cent, against 44 of the 582 cases of diabetes in the white, 7.56 per cent, the reduction undoubtedly being due to the wider and more intelligent use of insulin in these later years. The mildness of our climate too, may play some part for our general incidence for both races of 9.4 per cent is decidedly less than the 13 per cent which Eliason reports in his cases.

The incidence of syphilitic disease in the South is generally admitted, and syphilitic patients, it is generally admitted, are prone to develop arterial disease earlier than their uninfected brothers. Joëlin many years ago made the point that diabetic patients with gangrene show a positive Wassermann seven times as frequently as do diabetic patients without gangrene in his whole

Fig. 1. Left, average age of onset in various types of gangrene. Right, average age of death in various types of gangrene.

series only 2.8 per cent of all diabetics exhibited gangrene against 10 per cent of syphilitic diabetics, but these figures Lemann was unable to corroborate for the South. In our own series, however, 16 patients in the senile arteriosclerotic group of 110 cases 13.6 per cent had positive Wassermann reactions and 12 of them were negroes. Two of the 45 diabetics, both negroes, also had positive tests, and we have no doubt that the number in both groups would have been materially increased had the past history of syphilitic infection been considered as well as the present laboratory manifestation.

Eliason's and Wright's statement that diabetic gangrene ensues approximately 10 years earlier than the arteriosclerotic variety we have found to be true as Figure 1 shows. The average age in the arteriosclerotic group was 64.2 years, 66.7 years for the white against 63.7 years for the colored while in the diabetic group the average age was 56 years, 64.5 years for the white against 51.9 years for the colored the discrepancy between the white and the colored age of onset being particularly striking in the diabetic group. In this same connection, it might be mentioned that the arteriosclerotics with positive Wassermann reactions exhibited their gangrene at an average age of 61.3 years and the diabetics at an average age of 42 years which is well below the average age for each group. The single patient with Buerger's disease who had a positive Wassermann reaction was only 28, although the average age for the group was 42.5 years.

Since the risk of surgery for gangrene increases with age it is not surprising to find (Fig. 1) that the average age of death in the arteriosclerotic group was 67.8 years more than 3 years more than the average for the whole group. The age

limits of the arteriosclerotic group ranged from 43 to 91 years, as contrasted with 37 to 84 years in Eliason's group, and from 31 to 74 years in the diabetic group, as contrasted with 34 to 79 years in Eliason's group.

The arteriosclerotic variety of gangrene is overwhelmingly more frequent in the male, 90 against 10 cases, while the diabetic variety is more frequent in the female 28 against 17 cases. All the cases of Buerger's disease occurred in white males. It is rather interesting that the average age of the females with arteriosclerotic gangrene was 69.2 years while the male age was considerably lower 63.4 years, and that in the diabetic group the average age of the female was 55 years against a male age of 51.3 years. The latter discrepancy is worth noting in view of Eliason's and Wright's conclusion that the female with diabetic gangrene runs more risk at an earlier age than does the male with the same condition.

Table I which shows the mortality in relation to the underlying disease is self-explanatory. From Figure 2, which shows the mortality and the development of secondary gangrene in relation to the site of amputation certain conclusions may be drawn. In arteriosclerotic gangrene if one is sure that the vascular occlusion is confined to the digital branches, conservatism can be safely

TABLE I.—MORTALITY IN RELATION TO DISEASE

Disease	Cases	Deaths	Mortality rate
Arteriosclerotic		43	50.6
Diabetic	45	19	42.2
Buerger	4	3	75.0
Embolic	2	2	100
Total	71	67	94.4

Fig. 2. Left, mortality rate of amputation at various levels. Right, incidence of recurrent gangrene at various levels of amputation.

practiced for the chances are that it will be successful and the risk of reamputation, though naturally greater is still not excessive. In the diabetic, on the other hand in whom the initial disease is more serious and in whom the tendency of the wound to heal is militated against by his constitutional disease the situation is much more serious it apparently cannot be taken for granted that the gangrenous process is localized, and reamputation carries with it a very serious risk. Finally the point we made originally is corroborated by these figures, that the higher the amputation is done the less is the risk of recurrent gangrene but the greater is the mortality. In Eliason's series reamputation in arteriosclerotic gangrene carried a mortality of 10 per cent against an original mortality of 34.2 per cent whereas in the diabetic group it carried a mortality of 50 per cent against a mortality of 35.1 per cent for the first operation.

The 14 cases of Buerger's disease deserve some special comment. In the 2 cases in which fingers or toes were amputated at intervals, there was no mortality. In the 7 cases in which amputation was done on the leg there were 3 recurrences, necessitating 2 reamputations, and there was 1 death from a streptococcal infection of the stump. In the 5 cases in which amputation was done at the thigh there was 1 instance of recurrent gangrene, and 2 deaths, 1 from lobar pneumonia in 4 days, and another 37 days after operation from an infection of the stump associated with pulmonary embolism and septic infarcts of the lungs, liver and kidneys. The high percentage of recurrences seems to prove the point made by a number of writers that amputation in this disease should be deferred until the limits of the process are clear.

Studying the mortality from the point of view of the time at which it occurred we find that 9 of

the 43 deaths in the arteriosclerotic group occurred within 24 hours, from shock, usually associated with toxemia, in 8 cases, and from cardiac failure in 1. Eight of the 19 diabetic deaths occurred within 24 hours from shock in 4 cases, the diabetes being under perfect control, and from diabetic coma in the other 4 associated, in 1 case, with a pre-existing gas bacillus infection. The immediate surgical mortality therefore in these two groups is 17.99 per cent, as compared with 3.6 per cent in Eliason's and Wright's 1936 series, and 3.5 per cent in Eliason's 1933 series, which includes only diabetics, this disproportion being rather interesting in view of the fact that the final mortality rates are not very different, 39.1 per cent for the Charity Hospital cases against 33.3 per cent for Eliason's arteriosclerotic cases, and 43.6 per cent for his diabetic cases.

Of the 19 arteriosclerotic deaths which occurred from 2 to 10 days after operation 10 were due to pneumonia, 4 to uremia, 2 to cardiac failure, 2 to recurrent gangrene and toxemia, and 1 to gas bacillus infection. Of the 7 diabetic deaths which occurred within the same period 3 were due to diabetic coma, 3 to recurrent gangrene associated in 2 cases with septicemia, and in 1 with pulmonary abscesses and otitis media, and 1 to pneumonia.

Of the 15 arteriosclerotic deaths which occurred after 10 days, 9 were due to pneumonia, 2 to cardiac failure, 2 to renal complications, and 2 to recurrent gangrene and toxemia. Of the 4 diabetic deaths which occurred in this period 2 were due to diabetic coma and 1 each to recurrent gangrene and toxemia and to myocardial failure and cerebral embolism.

To summarize and as Figure 3 shows, in the arteriosclerotic group shock and pneumonia were responsible for the greatest number of deaths, while in the diabetic group diabetic coma was

Fig. 3 Causes of death in various types of gangrene

responsible for almost 50 per cent. The contrast with the arteriosclerotic group is illuminating but rather shocking in these days when diabetic coma is supposedly a condition within medical control. Undoubtedly the explanation is the tendency of these patients to delay entrance to the hospital or to refuse surgery when it is offered to them. The last 2 diabetics who died on our own service died because they themselves refused operation until it was too late not realizing that in this disease the mere existence of gangrene and infection constitutes a threat to life and that the risk increases with every day that operation is postponed.

Only 2 cases in this whole series developed gas bacillus infection which was surprising to us in view of the 14 cases reported by Eliason 10 of them postoperative in his 175 cases. There is undoubtedly in this disease a sort of seasonal incidence our statistics end with December 31, 1933 and during January and February of 1934 we had on our own service 3 patients with gas bacillus infection following amputation 2 of whom died and the inclusion of whom would have materially altered our percentage. How or why these patients developed the infection we do not know though its occurrence in the cold months when blankets are in use naturally makes us think of Gage's brilliant work on the introduction of the infection from the contact of an open wound with woolen goods even after it has gone through all the processes of manufacture. That more of our colored patients do not develop this particular contamination is rather surprising for

the ward is overcrowded they have the most elementary ideas of hygiene and the soil seems ripe for it.

Certain explanations for our very high death rate immediately present themselves. Age is a factor which cannot be controlled and patients advanced in years with associated degenerative diseases of the heart and kidneys are bound to exhibit a higher mortality than younger subjects. Furthermore, they endure rest in bed badly, both before operation and after and are particularly prone to develop a hypostatic pneumonia which is likely to carry them off. This was recently proved by one of our own colored male patients. He entered the hospital in a deplorable state, which is not unusual, he refused operation for more than a week, and he developed a post operative gas bacillus infection which due to the carelessness of an interne was not reported to the staff man for more than 8 hours. For several days following the second amputation he was seriously ill and he weathered the postoperative storm only to lose his life 10 days later from a hypostatic pneumonia.

Our figures show that the duration of the gangrene provided toxæmia and infection are not associated factors, has surprisingly little effect on the mortality rate but that its extent (Fig. 4) is the most important single consideration in determining the outcome. For that extent as we have said several times, the surgeon is sometimes responsible but the patient more often is partly because he delays seeking medical advice partly because he refuses to follow the advice that is

Fig. 4 Relation of extent of gangrene and mortality

given him. Once gangrene is established beyond hope of recovery the single most important factor in reducing the surgical mortality is the promptness with which operation is done. Two things cannot be too often emphasized that a diabetic operation is allowed to pass by and that neither may lose his life because the optimum time for operation is allowed to pass by and that neither diabetes nor aged arteriosclerosis tolerate toxemia well. The degree of the constitutional reaction seems almost as important as the extent of the gangrene. Eighty-two per cent of the patients who died in this series had a febrile reaction above 100 degrees F before operation while only 25 per cent who lived exhibited it the longer the reaction endured the higher the mortality.

Careful pre-operative preparation is essential. The preparation of diabetic patients is standardized and should be in the hands of the surgeon internist who works in full accord with the surgeon. Medical matters are the business of the internist but the surgeon must remember that when the diabetic is sick of other diseases, particularly diseases in which infection is a factor the usual reliance cannot be placed on insulin and his work must be done as expeditiously as possible. In the arteriosclerotic group as we have already mentioned, we have begun to study fall in the mortality since we have begun to study before operation the kidney function and general condition and to force fluids before and after operation. We are careful also to move these patients about in bed and to get them up as promptly as possible to guard both against pneumonia and against decubitus ulcers.

We do not believe that any death in this series could be attributed to the anesthesia used, although there seems no question that spinal analgesia or nitrous oxide or ethylene anesthesia is the agent of choice. Ninety-nine cases were done under spinal analgesia, 37 under ethylene, the remainder under local ether or nitrous oxide.

The type of amputation seems to have considerable bearing upon the recurrence of gangrene and the development of sloughs, which is to be expected for many of these patients have an actual or a latent infection when the operation is done, and postoperative infection is likely in any tissue in which the simple circular type of amputation is wisest for all amputations except those on the fingers and toes, and a careful study of these records convinces us of the correctness of our contention. This is the old *en sautoir* method of the French writers, which was described several years ago by Urban *Mac* in a paper on surgery in diabetics. The chief point of the operation is that the lines of section are made at right angles to the long axis of the limb which means, since the blood vessels of the extremities in passing to the tissue plane do so more or less at right angles, that no tissue is left without its blood supply. The procedure is quite simple technically. The skin is incised, then allowed to retract. The muscles are sectioned at the level of the retracted skin then allowed to retract. Finally the bone is sectioned at the level of the retracted muscle. To express it differently in each plane the section is made at a higher level so that the final effect is that of an inverted cone. With this technique with individual rather than *en masse* ligature, and with loose closure by three or four sutures over the face of the stump, it is rarely necessary to employ drainage.

SUMMARY AND CONCLUSIONS

1. Gangrene of the extremities in private and public practice introduces very different problems. A new conception of arterial vascular disease is essential on the part of both public and profession but the mortality is not likely to be reduced nor is the incidence of mutilating surgery until patients present themselves earlier for treatment and until physicians recognize the significance of premonitory symptoms.
2. One hundred seventy-one cases of varicose types of gangrene have been studied in detail with particular relation to the pathology exhibited, the predisposing causes, the racial incidence the mortality of amputation and the recurrence of gangrene after it.

3 The high death rate is attributed to delay in seeking treatment and in accepting surgery, and to the age and the concomitant cardiac and renal diseases of arteriosclerotic patients and the metabolic disease of diabetic patients the extent of the gangrene being the single most important factor. Anesthesia other than ether seems to play no part in the mortality, but the type of operation does, and the simple circular amputation is the one that is recommended.

A POSITIVE TREATMENT FOR FRACTURES OF THE SHAFT OF THE FEMUR

A PRELIMINARY REPORT EMPHASIZING AMBULATORY TREATMENT

R. A. GRISWOLD M.D. F.A.C.S. LOUISVILLE, KENTUCKY

From the Department of Surgery, Louisville City Hospital and the University of Louisville School of Medicine

FRACTURE of the shaft of the femur presents a problem in mechanics which is often difficult of solution. The almost universal method of traction and suspension is far from ideal. There is no positive control of either fragment and accurate reduction is difficult and sometimes impossible. Frequent readjustment of the apparatus is essential to maintain position and requires almost hourly care. Long hospitalization is the rule and is a distinct economic drawback. Reduction and fixation by plaster cast is satisfactory in cases in which the fragments can be locked. Often however slipping and displacement occur within the cast. These considerations have led many surgeons to advise open reduction with internal fixation as a routine measure. Experience with a new method of treatment of fracture of the tibia and fibula has led to the development of a somewhat similar procedure for the femur. For fractures of the tibia and fibula counter traction is applied by a steel pin through the proximal fragment, and traction rotation and angulation by a pin through the distal fragment or os calcis. Incorporation of these pins in a plaster cast effectually prevents subsequent displacement. In the application of this principle to the femur traction and countertraction have been applied at the ankle and perineum. Pins through the proximal and distal fragments have been used only for manipulation and fixation.

Deformities in fracture of the femur are due to the fracturing force and to muscle pull. The latter replaces the former when the length of the limb is restored by traction and is, therefore, the more important (Fig. 1). The deformities are shortening rotation angulation and transverse displacement. They may be influenced by the direction of the fracture plane. Shortening is produced by the entire group of longitudinal thigh muscles and presents few difficulties if efficient extension is available. The proximal fragment is usually rotated outward, especially in high fractures, by the action of the external rotators of the hip. The distal fragment may be rotated in either direction by the weight of the foot but is usually everted. After the normal length of the limb has been restored and rotation corrected,

displacement may be viewed from anterior and lateral aspects. From the anterior aspect it is due to the action of the abductors of the hip and the adductors attached to the shaft. If the fracture is high the proximal fragment is abducted and the distal fragment adducted, thus producing outward bowing. If low the proximal fragment is often adducted in relation to the distal fragment which is held in line by traction. From the lateral aspect the deformity is due to anterior flexion of the proximal fragment by the iliopsoas and posterior flexion of the distal fragment by the gastrocnemius group. Flexion of the proximal fragment is most marked in high fractures and of the distal fragment in low fractures.

The first principle of the usual non-operative treatment is to restore the length of the limb by extension. This corrects transverse displacement by the squeezing effect of the taut musculofascial tube in which the bone lies. The second principle is to bring the distal fragment into line with the proximal, leaving them both in their positions of muscle equilibrium. This is accomplished from the anterior aspect by abducting or adducting the distal fragment. From the lateral aspect the lower fragment is brought into line by flexing the knee to relax the gastrocnemius and lifting the fragment anteriorly to appose it to the flexed proximal end. Rotation is easily controlled by various means. Maintenance of the fragments in this position is then attempted by continuous traction or a plaster cast.

The method here presented gives accurate mechanical control of the proximal as well as the distal fragments. Firm, uninterrupted fixation is provided until healing occurs. The position is that of normal weight bearing rather than that of muscle equilibrium. Immediate ambulatory treatment is possible. The latter is important aside from the economic advantage of short hospitalization. Weight bearing encourages healing and prevents to a large degree the atrophy associated with immobilization. The natural physiotherapy obtained by the use of the extremity is superior to any form of artificial physiotherapy in maintaining the nutrition and tone of the tissues. When a walking cast is removed the strength of

the extremity and the range of motion at all joints is often surprising. It is not unusual to have immediate complete range of motion at the hip and ankle and 45 degrees of painless active motion at the knee. Measurement of the circumferences of the thighs and calves show little or no atrophy. This is superior to the state after removal of the usual padded, non-ambulatory cast, and at least equal to that following traction suspension methods.

PROCEDURE

1. Under spinal or local anesthesia the patient is placed on the fracture table and extension applied until the length of the limb is restored. This is obtained by Collin's hitches about the ankles and countertraction against the ischium of the well side.

2. After preparation of the skin a steel pin, $\frac{1}{8}$ inch in diameter and 6 to 8 inches long is inserted transversely through the distal fragment just above the adductor tubercle. A second pin, $\frac{5}{32}$ inch in diameter and 8 to 10 inches long, is inserted in the anteroposterior direction at or slightly below the level of the lesser trochanter. If placed above this point, the soft cancellous bone will not stand the strain imposed upon it. This pin is well lateral to the femoral vessels and sciatic nerve, the only important structures in this region. Accurate placement is best aided by the fluoroscope. These pins are inserted directly through the skin. Incisions are unnecessary and invite infection. Restoration of the length of the limb before insertion of the pins is important to prevent skin tension. Small alcohol or collodion dressings may be applied about the pins.

3. The distal pin is slung from the suspension bar of the table by a suitable caliper and lifted to correct flexion of the distal fragment. Flexion of the proximal fragment is corrected by a clockwise motion of the upper pin which is held manually in a caliper (Fig 1a). From the anterior aspect the deformity is corrected by abduction or adduction of the distal fragment combined with medial or lateral traction on the proximal pin (Fig 1b). Rotation is corrected by appropriate motion of one or both pins.

4. The position is checked by fluoroscopy or roentgenograms in two planes and any necessary residual correction carried out. It is occasionally advisable to overextend the extremity during manipulation so that there is a space between the fragments. This facilitates reduction in irregular fractures, but as soon as proper position is obtained traction should be decreased so that the fragments firmly abut each other.

Fig 1. The usual displacement in fracture of the shaft of the femur after length of the thigh has been restored viewed from A, the lateral aspect and B the anterior aspect. The sites and positions of the pins are indicated. Arrows show the directions in which force is applied to the pins for reduction.

5. A non-padded walking spica is applied following the method outlined by Boehler and Schnek. The anterior superior spines and sacrum are protected by thin padding which is covered by a circular layer of flannelette extending from the xiphoid to the symphysis. A previously prepared roll of padding is applied to the tuberosity of the ischium for counterpressure. This is made by tightly rolling an 8 by 5 inch oblong of silence cloth over the center of a 3 foot length of bandage and covering it with adhesive tape. The pad is about 8 inches long and the thickness and firmness of a Thomas splint roll. The long ends of the bandage are pulled snugly upward over the flannelette so that the pad impinges firmly against the tuberosity. Circular plaster bandages are applied to the trunk and pelvis and molded about the crest and spines of the ilium. Anterior and posterior splints are applied to the skin from the Collin's hitch well up over the pelvic portion of the cast and covered with circular plaster bandages closely incorporating both pins. On the perineal side of the thigh, plaster is modeled over the ischial roll to form a shelf like structure which holds the roll in place and transfers some of the pressure of weight bearing to the ischium after the manner of a Thomas walking caliper. The remainder of the weight is taken up by the pins. The junction of the thigh and pelvic portions of the cast is strengthened by additional splints and bandages. When this plaster has set the Collin's hitch is removed and the cast extended.

An anterior plaster splint is applied as far as the base of the toes and a posterior one to a point $\frac{1}{4}$ inch beyond the tips of the toes. These are covered with circular plaster making firm union with the rest of the cast. A Boehler walking iron is incorporated as soon as the plaster has hardened. Trimming of the cast is carried out to uncover the upper abdomen and allow free motion of the uninjured thigh. Accurate and proper molding of this type of cast is essential, especially about the pelvis, knee, and ankle. One should have considerable experience with the smaller non-padded casts before attempting a spica. The cast should be as light as is consistent with strength. Properly constructed for an adult of average size it weighs 12 to 14 pounds, and is considerably stronger than an equally heavy padded cast on account of the more evenly distributed stresses (Fig. 2, 10, 13).

6 Weight bearing is allowed as soon as the plaster is sufficiently hard and roentgenograms have checked position in the cast. In healthy young adults and children this is usually about the third day. Two crutches are used at first, later to be exchanged for canes as the patient gains confidence. Children not infrequently require no external support after a week or two. Weight bearing should be painless after the first few days. If it is not there may be some defect in the cast or reduction. The most probable cause of pain is insufficiently firm fixation of the pins in the cast allowing motion. The cast remains in place throughout the period of healing and may take the place of a convalescent walking splint. The pins may be removed at the end of about 8 weeks.

7 Feeble elderly individuals may be too weak to carry a cast and so not able to avail themselves of the advantages of ambulatory treatment. In this case the pelvic portion of the cast may be omitted or removed leaving the ischial pad and maintaining firm fixation of the proximal pin. It is possible that pivoting of the proximal fragment on the pin might occur with resulting outward bowing. This has not occurred in two cases so treated, but I feel that omission of the pelvic cast is advisable only if the patient cannot walk, and when it is essential to allow him to sit up in bed or a wheel chair.

APPLICATION OF METHOD

Putti has utilized a method for operative lengthening of the femur in which he places proximal and distal pins for traction and counter traction. It should be noted that in the technique for fractures described in this paper no traction

is applied to the pins so that they are left perfectly free for manipulation. The evolution of this method of treatment was necessarily gradual. The reduction of suitable fractures by manipulation and fixation in a spica cast was the natural starting point. The first additional step was to correct the posterior angulation of the distal fragment in fractures of the lower third of the femur by a steel pin as described by Anderson. In cases so treated bowing was found to occur with weight bearing. This was due to settling of the thigh into the cast despite the ischial pad (Case 1). The next development was skeletal control of the proximal fragment making the method applicable to all fractures of the shaft and effectively preventing displacement or bowing. "Mechanical hands" which may be firmly attached to arms from the table have been designed to manipulate and hold the pins until the plaster has set. These will eliminate the cumbersome method of hanging the distal pin from the suspension bar of the table by a rope and manually controlling the proximal pin. Some surgeons are not familiar with or are not convinced of the advantages of the non-padded cast and ambulatory treatment. For their benefit the pins may be used with the padded type of cast, adding the advantages of accurate reduction and firm fixation to their previous techniques.

This method has been applied to 10 cases. Five of these were not made ambulatory because of psychosis (3 cases), other fractures (2 cases), and transfer to another hospital shortly after reduction (1 case). The 5 other patients first walked with weight bearing on the second to the fifth day except one patient with a compound (gunshot wound) fracture who walked on the eighth day following fracture and the first day after application of plaster. Healing in good position with excellent functional result is known to have occurred in all these cases except the one transferred elsewhere. Hospitalization has been reduced to a minimum, averaging about 12 days for patients who did not have co-existing disease or injury for which hospitalization was required. The following cases have been selected to illustrate (1) anterior bowing due to weight bearing when the proximal pin was not used (Case 1), (2) use of the procedure when the patient cannot be made ambulatory (Case 2) and (3) typical ambulatory treatment (Cases 3 and 4).

CASE REPORTS

CASE 1. A P. aged 28 years, Hospital No. A 7464, was admitted with an irregular transverse fracture at the junction of the lower and middle thirds of the left femur with acute posterior angulation of the distal fragment and no

position (Fig. 3). Under spinal anesthesia the length of the limb was restored by traction on the Hawley table and the displacement corrected by manipulating a steel pin which was passed through the distal fragment. A Boehler spica was applied incorporating the pin. He was allowed up on crutches on the fourth day and discharged on the eleventh day. Roentgenograms at this time showed acceptable alignment and position except for some anterior bowing. At the end of 1 month he was walking well with two canes (Fig. 2) and there was good callus. The pin was removed on the fifty-eighth day and the cast on the seventy-fourth day. At this time union was firm, there was 90 degrees of motion at the hip, 45 degrees at the knee, and complete function of the ankle. There was no shortening. At the end of 5 months, the function of the hip and knee was normal (Figs. 4 and 5).

CASE 2. K. K. aged 15 years, Hospital No. 3, 157 was admitted with a transverse fracture of the middle third of the left femur with 5 inches of overriding (Fig. 6). There were associated fractures of the left superior ramus of the pubis, the middle third of the right tibia and fibula and the first, second and third metatarsals. Under spinal anesthesia the fracture of the right leg was reduced and placed in non-padded plaster cast. Traction was applied to the fractured metatarsals by wires passed through the pulps of the toes and rubber bands fastened to an outrigger on the cast. The length of the left thigh was restored to normal by traction on the Hawley table. A steel pin was passed transversely through the distal fragment at the level of the adductor tubercle and another in an antero-posterior direction opposite the lesser trochanter. The fracture was reduced by manipulation of these pins and a non-padded spica was applied. Post reduction roentgenograms showed satisfactory position of all fractures except slight deformity of the distal extremity of the second metatarsal. He was discharged home on the seventh day. He was readmitted for one day on the twenty-fourth day for removal of the wire traction from his toes and repair of the spica which had cracked at the groin. On the sixty-fourth day he was readmitted for 2 days and the casts and pins were removed. There was good union of all fractures but slight lateral angulation of the tibia. When seen again at the end of 4 months he was walking well without support with a slight limp but no pain. The thighs were of equal length but there was 1/2 inch shortening of the right leg and a right pes planus. Flexion of the right knee was complete. The left knee was limited to 90 degrees. The range of motion of hips and ankles was complete. There was firm healing and good position (Fig. 7).

CASE 3. E. B. aged 42 years, Hospital No. 32, 504, was admitted with an oblique fracture at the junction of the upper and middle thirds of the right femur with 1 inch overriding (Fig. 8). Reduction was carried out in the usual manner on the Hawley table under spinal anesthesia, 2 pins being used and incorporated in a walking spica. She was allowed up on crutches on the third day (Fig. 9) and discharged home on the eighth day. The pelvic portion of the cast was removed on the forty-fourth day. The pins and remainder of the cast were removed on the sixty-fourth day. At this time union was firm. She continued up on crutches. At the end of 3 months she was walking well and had good union with slight anterior bowing. There

was 90 degrees range of motion at the knee. Limitation of the hip was considerable as a result of pre-existing arthritis (Fig. 9).

CASE 4. A. B. aged 20 years, Hospital No. 33, 580, was admitted with fracture of the middle third of the right femur with 2 inches of overriding (Fig. 11) and multiple lacerations. The lacerations were debrided and sutured and traction applied to the injured thigh under spinal anesthesia on the Hawley table. Pins were inserted through both fragments in the usual manner, the reduction completed, and a Boehler spica applied. He was allowed up on crutches on the third day (Fig. 12) and discharged home on the tenth day. Roentgenograms showed satisfactory position (Fig. 13). He was readmitted on the sixty-fourth day on account of a carbuncle near the edge of the medial pad. The pins and cast were removed to allow incision and drainage. Position was good, but union was not yet firm enough for unsupported weight bearing. Three weeks later the carbuncle was healed and union was strong enough to allow walking on crutches with guarded weight bearing.

CONCLUSIONS

1. A new method of positive mechanical reduction for fracture of the shaft of the femur is presented.
2. Firm, dependable fixation is maintained throughout the period of healing.
3. Ambulatory treatment is feasible giving the advantages of continuous physiotherapy.
4. Anatomical and functional results in a small series have been excellent.

Since this paper was submitted for publication June 11, 1934, McWhorter has reported the use of a pin through the greater trochanter which is fixed in plaster after reduction of the fracture on the Hawley table. His key has also described an apparatus for applying skeletal traction and counter traction to the femur with pins in both fragments. Further experience with the method I have described leads me to believe that it is important to restore the length of the limb before inserting the pins. This will prevent pressure necrosis of the skin about the pins. It is also advantageous to leave the pins free of traction force to allow easy and accurate manipulation.

THE CLOSURE OF CHRONIC OSTEOMYELITIC CAVITIES
BY PLASTIC METHODS

JOHN PRENTISS LORD, M.D., F.A.C.S., OMAHA, NEBRASKA

A SIMPLE serviceable measure for effecting healing in bone cavities is by skin grafting first used by the writer in 1901 before either saucerization or skin grafting was recommended or popularized (3).

Figure 2 represents a bone cavity in an acetabulum and the partially excavated head and neck of the femur in a woman 60 years of age who had had a discharging sinus for 50 years due to hip disease from infancy. In later years it had become a large persistent residual abscess because the innumerable curettings and excavations resulted in its progressive enlargement thus decreasing the possibility of healing the putrid bony cavern. The cavity which was 7 centimeters deep was healed by the introduction of plastic skin flaps, and supplemented by skin grafts. The method employed resulted in the permanent healing of this almost life long problem case (Fig. 2B).

Among the simplest of the defects to be closed following operations for osteomyelitis is the gutter remaining in the tibia due to the removal of the diseased tissue of the anterior and interior portions of the bone after it has been saucerized. The gutter may be long or short. It sometimes extends the whole length of the tibia.

It is represented in the upper third in Figure 4. The common textbook treatment of this condition is to gutter the bone—that is to excise by saw and chisel the diseased portion and remove sufficient of the cortex to render the cavity more shallow after which our usual method is to turn in the skin edges to meet at the bottom of this gutter to cover the bone surfaces and thus effect early healing and closure.

In some chronic cases in which operation had previously been done, greatly enlarged bones sometimes covered with extensive exposed scars had frequently become abraded and ulcerated. Having seen 2 cases of cancer develop from such scars repeatedly traumatized I have had a wholesome fear of allowing a workman to carry such a scar on the surface of his shin. In the case of a greatly enlarged osteomyelitic tibia, many times recurrent (not here illustrated) there was a wide scar area of parchment like ulcerated skin which necessitated wide excision after which there was insufficient sound skin to fill the usually wide gutter completely. Therefore their

margins were freely undercut but still their edges would not meet at the bottom of the gutter with out too much tension. Lateral incisions were therefore made and undercut to release the flaps so that the skin margins would coapt. For fastening these skin edges I commonly use carpet tacks of a large size or small nails or brads after the method of Neuber. Sometimes however the bone is so hard and eburnated that an ordinary tack may be broken off in which case it may be necessary to make small drill holes to receive the brads or tacks. The remaining lateral skin defects after relaxation cuts if wide may also require skin grafting in case they cannot be later coapted by the sutures primarily left untied (Fig. 3A).

Figure 4 represents a persistent cavity in the upper end of the tibia. A large perforating defect extended through the tibia to a sequestrum behind the bone thus leaving a very large cavity difficult to fill. Nature will begin the closure of such a large cavernous defect in the interior of the bone by granulations and succeed to a certain point, but there will remain an infected cavity or sinus, persistent sinuses may remain indefinitely. Recureting fails, because the cavity may have become too large to be healed unaided by nature's processes, and it must be filled by transferring tissue. Where transfer of muscle and other tissue was too difficult and impracticable I have effected healing in some of these cases as follows. By the incisions as shown in Figure 4A, flaps were made from above and below which were turned into the excavated area (Fig. 4B). This technique was used after the cavity had been débrided and lined with granulations. The interior was healed by these skin flaps and a dry cutaneous tract secured by adopting the principle of Beck, which was used by him in the treatment of extensive empyemas. These flaps were turned into the cavity the skin surfaces facing each other but not in close contact. Thus a skin lined tract was secured and the coapted flap margins rapidly healed. The opening having been circular these margins were readily brought together and a permanent healing obtained. These procedures reduced the period of hospitalization to a minimum. One such patient had been afflicted for 14 years. A sequestrum in the upper portion on the

Fig. 1

Fig. 3

posterior surface of the tibia, had left a large tunnel through the bone from eight previous operations which resulted in successive increases in its size and presented a perplexing problem. The procedures here outlined turned out very well in these cases. Thus seemingly incurable discharging bone cavities were finally and permanently healed in a satisfactory manner. The cavities in the tibia were too high and inaccessible for muscle flaps. The skin-lined tracts (Fig. 4C) gave no inconvenience.

Figure 5 illustrates the preparation of an extensive cavity in the femur and shows the method of securing the flaps. This technique is not new but from my observation is little practiced. It is

my conviction that a person who has had osteomyelitis for 10 or more years, with discharging sinuses and recurrences every year or two, is entitled to an early expeditious and permanent cure if such is possible of achievement. The removal of the diseased and infected area in cases of long standing by careful excision, leaves little chance for contamination and, if infection does occur it should lack virulence after years of self-immunization. For these reasons, liberties may be taken in making immediate closures. Therefore it has been my custom to make primary plastic closures by securing tissue as shown in Figure 6A, and turning the flaps of fascia, fat, and muscle secured from the median and lateral thigh surfaces, into the cavity, closing the skin flaps over all in one procedure. (Fig. 5B and C). In some extensive cases, in which the process involved the whole of the interior of the shaft, as shown in Figure 6A it has been necessary to turn in tissues from both sides and appose the deep flaps, filling the large cavity completely and closing the skin as in Figure 5B.

The following case, a still more extreme one of the type just described, will demonstrate its fuller extent. The process invaded one-half of the femur and involved the condyles to such a degree that the disease extended to the cartilages, and there remained but shells of the condyles. Ankylosis of the knee had resulted from the effects of the disease, which had existed for 24 years. The

Fig. 2

Fig 4

Fig 5

apices of the flaps composed of fat ligaments and underlying soft parts over the ankylosed knee joint including periosteum over the condyles and tuberosities of the tibia, provided extra length to the flaps of the vastus internus and externus. The extra length of these very long flaps was secured by extending the longitudinal incisions in the skin and ligaments below the knee joint 1 5 inches the skin had been reflected and deep flaps of fat, fascia, and periosteum were taken from the lateral surfaces of the ankylosed knee. The femur and condyles had been completely excavated from both sides. These long flaps were then turned from each side into the hollowed lower femur and folded transversely within the cavity of the condyles so as to fill completely this portion of the very large space. The fascia, aponeurosis and muscles were sutured together as well as to the wound margins to prevent their retraction. Thus, by using these large amounts of additional soft tissues to elongate the flaps of the vastus muscles the enormous cavity in the lower half of the femur and extending into the condyles was filled. Aided by dakinization delayed or delayed primary union was obtained. Figures 6A and B illustrate the method of closure and Dakin tubes as shown in Figure 5C.

In earlier work I regularly introduced Dakin tubes and to prevent their immediately becoming clogged with clots which would nullify their efficacy it was my custom to start irrigation immediately with a 2 per cent solution of sodium citrate and continue it until the Dakin irrigation was established in order to be sure of having patulous tubes. By employing this technique in these

cases a sterile wound was maintained and healing by delayed or delayed primary union was immediately accomplished, permitting the discharge of the patient in 3 weeks. The patient with the severe condition referred to has remained well Previous to being treated as outlined this man had suffered from constantly discharging sinuses with recurrences every year or two for a period of 24 years. In a similar case the wound closed promptly after 35 years of sinuses and recurrences. A series of 16 cases somewhat alike have been thus successfully closed by what I have termed delayed primary healing.

These operations may vary in degree according to the extent of the disease and must necessarily

Fig 6

vary in their application. I have found dakinization very useful in many cases, but in some of the more chronic cases I have not used it. I have simply coapted the wound rather loosely and left it patulous, and have succeeded without dakinization. It is a matter of judgment as to whether or not one need employ Dakin's solution. In a few cases, hypertonic salt solution has furnished a satisfactory substitute. Needless to say, my judgment has failed me in some cases in which I had become too bold, and had used no antiseptic irrigation.

The plastic closure of osteomyelitic cavities by bone and soft tissue, I repeat, is not new. Experience has led me to use it in the manner described with variations in selected cases, and the results have been obtained by a primary loose closure of the cavity rather than by a period of primary dakinization and closing by a secondary procedure.

One of my principal objects in this work has been to limit the stay of the patient in the hospital and secure an early permanent healing.

In the late war it was found very desirable to treat wounds with Dakin's solution after débridement and when the field became clean the plastic work was done as a secondary operation. In civil

life, many of our cases are of the chronic form, and repeated operations have been done, the patients having gotten well of the acute disease, but continuing to be harassed by recurrences or by draining sinuses. As previously stated, it is my conviction that such long suffering individuals are deserving of permanent cure and that the operations, therefore, should be radical if necessary to effect it. In the chronic cases, when infection is not particularly to be feared and the patient has become presumably relatively immune from the remaining organisms, one may in a primary operation do the excavating and plastic closure as one procedure and secure, at least delayed primary union. In chronic osteomyelitis involving the whole interior of the bone whether it be of limited or great extent the cavity may be filled by muscle and fat and sometimes bone, after thorough removal of the disease. The complete closure and healing of the wound in some cases need not require more than 10 days or 2 weeks.

OPERATIVE INJURIES OF THE URETER¹

IRA R. SISK, M.D., F.A.C.S. MADISON, WISCONSIN

ALTHOUGH a review of the literature reveals numerous reports of operative injuries of the ureters it is probable that relatively few cases are recorded. This discussion deals briefly with the treatment of some types of such injuries and is based on the observation and treatment of 5 cases.

In considering the question of operative injury of the ureter either from the standpoint of prevention or treatment, the important thing to be kept in mind is the preservation of renal function. Before entering upon a discussion of the treatment of these injuries means of preventing them should be mentioned. The presence of a catheter in the ureter during difficult operations in the pelvis will make it possible easily to avoid the ureter. For many years we have routinely inserted catheters in the ureters of such patients for the Department of Gynecology at the Wisconsin General Hospital and as a result only one ureter has been damaged (Case 4 of this series). In this case serious pathology was unexpectedly encountered and catheters had not been introduced.

In treating these injuries the genito-urinary surgeon encounters many difficult problems. The variations depend upon the age of the injury, its distance from the bladder, whether one or both ureters are involved and the type of injury, that is, whether it is completely severed, completely severed with the removal of a segment, partially severed, ligated or clamped. Suddenly confronted with the problem of dealing with a severed ureter many surgeons adopt the procedure of ligation as the best way out of the dilemma. Embarrassing circumstances are in this way avoided in many cases, but a kidney is rendered functionless. Further in some cases this treatment results after a lapse of a few days in urine draining from the ureter into the peritoneal cavity, or possibly finding its way to the outside, or infection in the kidney may necessitate surgical interference. The ligation of a cut ureter under circumstances favorable to repair should receive our most severe condemnation.

The method of repairing the ureter when the injury is discovered at the time of operation is for obvious reasons of the greatest importance. However, since the genito-urinary surgeon is rarely present when the injury occurs he will seldom have to deal with this situation. Simple ligation is justified only when the condition of

the patient is too bad to permit an operation for repair, for which, of course, more time is required.

A large number of operations have been described for the repair of this type of injury, but all are based on the principles of end-to-end, end-in-end or side-to-side anastomoses. As this operation will always be infrequently performed a simple method should be adopted and its principles thoroughly understood so that when called upon to repair a ureter the surgeon will not have to use a technique with which he is not thoroughly familiar. My first opportunity for repairing a severed ureter came suddenly. Fortunately a satisfactory repair was made and a normally functioning kidney was obtained (Case 1). Afterward in looking up the subject I found that I had adopted the technique described by Dr. Hugh Young. This technique seems to combine the principles of simplicity, splinting of the ureter, maintenance of caliber and satisfactory drainage. It is, I believe, the technique of choice for the repair of these ureters with certain exceptions which will be mentioned later. The technique is as follows:

A ureteral catheter as large as will freely move through the ureter without interfering with the circulation is introduced into the ureter and passed into the kidney pelvis. Introduction may be made through a cystoscope or the catheter may be passed each way from the point of injury, the lower end being brought out through the urethra later. Over this catheter end-to-end anastomosis is made with fine catgut, the sutures being passed through the serous and muscular layers. With satisfactory drainage the catheter may be left in place for many days to prevent contraction of the lumen during healing.

Exceptions are to be made when (1) the injury is sufficiently low to permit reimplantation into the bladder which is preferable or when (2) a segment has been removed of sufficient length to cause tension. If there is tension satisfactory healing will not occur and implantation into the bowel is the operation of choice.

In old injuries every case is a law unto itself. After appropriate examinations to determine the condition of the kidneys and ureters a satisfactory procedure must be selected. This may be a plastic repair, implantation into the bladder or bowel, nephrostomy or nephrectomy.

Fig. 1. Intravenous urogram made nearly 5 years after left ureter was completely severed and repaired. The kidney pelvis and ureter appear normal. Case 1.

CASE 1. Mrs. J. N., white female aged 24, was operated upon, April 9, 1929, by a general surgeon for an inflammatory mass of long standing which was located in the left side of the pelvis, having originated in the left fallopian tube. During the course of the operation it was discovered that the left ureter had been severed. Being in the hospital at the time, I was called, and with the wound still open passed a direct cystoscope into the bladder and introduced a No. 6 catheter into the left ureter. When this catheter reached the point of severance the surgeon introduced it into the proximal end of the ureter and it was passed to the kidney pelvis. The ends of the ureter were then anastomosed—end-to-end—with fine chromic catgut sutures, which were passed through the serous and muscular layers. There was never any leakage of urine at the point of anastomosis. The catheter was removed on the tenth day. Convalescence was smooth and uneventful. The patient was discharged from the hospital on the twentieth postoperative day in good condition. She has been seen at intervals since and has at no time had any symptoms referable to the kidney, and the urine has been normal. She was last seen in February, 1934, when she came for examination at my request. She was free of symptoms, the urine was negative, and intravenous urograms showed normal kidney pelvis and ureters.

CASE 2. Mrs. B. was operated upon by a general surgeon, August 1933, for the removal of an ovarian cyst. About 4 centimeters of the ureter which was attached to the wall of the cyst were removed. I was called at the time and inserted a No. 12 catheter through a cystoscope as described in Case 1. The ureter was repaired as in Case 1 but with considerable tension due to the removal of a piece of the ureter. On the seventh day a small amount of urinary drainage was noted on the dressing. There was no further drainage, and recovery seemed uneventful. The

Fig. 2. Retrograde urogram (reversed) showing normal right kidney and extra-urinary mass on left. This was made more than 2 months after the injury, the ureter having been repaired and the catheter left in the ureter for 15 days after the operation. Case 2.

catheter which had drained freely was removed on the fifteenth day and the patient went home on the nineteenth day with the wound well healed. Ten days later, however, she developed symptoms of frequent and painful urination and the urine was found to contain considerable pus. She was treated for several weeks with bladder lavage and urinary antiseptics, but was returned to the hospital on October 31, 1931, when she had a chill, fever and pain in the right side of the abdomen. On cystoscopic examination the right kidney was found to be infected with *Escherichia coli*. No urinary spurt was seen on the left side and though the left catheter apparently passed to the left kidney the urogram indicated that it passed into the per-ureteral tissues at the point of severance where it was coiled. The proximal end of the ureter apparently healed with occlusion as an intravenous urogram showed no evidence of flow in the left kidney pelvis and ureter.

CASE 3. Mrs. H. K., a white female, aged 45 years, had a vaginal hysterectomy and repair of cystocela by a general surgeon on March 24, 1931. Following the removal of a vaginal pack urine was noted from the vagina. From cystoscopic and other examinations it was determined that this was due to an injury to the left ureter. On October 7, 1931, through a left rectus incision the left ureter was isolated, freed, and re-implanted into the bladder. Convalescence was uneventful and the patient was discharged from the hospital on the twenty-first day in good condition. The patient has been seen at intervals since and has been free of symptoms referable to the urinary tract. She was last examined on April 15, 1934, when she was free of symptoms and the urine was normal. An intravenous urogram at that time showed good function in both lobes and very little dilatation in the left pelvis.

Fig. 3. Intravenous urogram 3 years after reimplantation of injured left ureter into bladder. The pelvis, calyces, and ureter are normal or very slightly dilated. Case 3.

Fig. 4. Intravenous urogram showing the presence of hydronephrosis on the left side which was the side injured. Case 4.

CASE 4. Mrs. C. M., a white female aged 46 years, was operated upon by a gynecological surgeon in November 1930, for a very large fibroid tumor. When ligating the left uterine vessels a structure thought to be a severed ureter was encountered. It was ligated, the abdominal wound was closed, and vaginal drainage instituted. A few days after operation urine began to drain through the vagina. Four weeks after operation an intravenous urogram revealed a large left hydronephrosis. A left nephrectomy was performed. Convalescence was uneventful. As large aberrant vessels were found going to both poles of this kidney it is probable that the vessel to the lower pole was at least partly responsible for the hydronephrosis.

CASE 5. A white female, aged 38 years, was first seen on June 24, 1931. She presented a letter from her local physician who stated that he performed an operation in March, 1931, for the removal of cysts from both broad ligaments. The left ureter was cut and repaired by invaginating the proximal end into the distal end. The wound healed but 10 days after discharge from the hospital severe chills and fever occurred, the wound re-opened and urinary drainage was noted. This continued. When we first saw the patient she was very acutely ill with temperature 103-104 degrees, chills, fever, nausea, and vomiting. There was free urinary drainage through the old abdominal incision. Urine was voided regularly. On cystoscopic examination urine was seen spurting from the left ureter and indigocarmine appeared in 9 minutes. A catheter met an impassable obstruction 3 inches above the bladder. No urine was seen coming from the right ureter and indigocarmine did not appear. A catheter met an impassable obstruction 5 inches above the bladder. A diagnosis was made of complete occlusion of the right ureter, probably the result of ligation, and left uretero-abdominal fistula, part of the urine from the left kidney draining into the bladder and part through the fistula. Operation was

performed on July 14, 1931. The left ureter was located and was found to be firmly adherent to the iliac artery for a distance of 1 1/4 inches; this was carefully dissected free. The fistulous tract which passed through the abdominal

Fig. 5. Retrograde pyelo-ureterogram, right. Case 4.

Fig. 6 Intravenous urogram. The left pelvis, calyces, and ureter are moderately dilated. No dye was excreted by the right kidney. Case 5.

cal cavity was dissected from the ureter and the peritoneum was closed. The ureter was then opened above the strictured area and the structure was widely dilated. Through the opening in the ureter a No. 10 catheter was passed upward to the kidney pelvis and downward through the bladder to the outside. The ureter was sutured and the wound closed with drainage. As a result of the free drainage the patient's condition in a few hours was better than before the operation. The catheter drained freely and in large quantities and there was no urinary drainage on the dressings. The patient died suddenly on the third post-operative day apparently from an embolus, though this could not be confirmed as autopsy was refused.

There are in the literature many case reports in which it is assumed that a satisfactory result has followed a ureteral repair but few in which the question is proved by appropriate follow-up examination. In 1929 Curtis reported a case in which a satisfactory result followed an end-to-end anastomosis and stated "I believe that this is the only recorded case in which end-to-end anastomosis of the ureter has been followed by clinical proof of normal kidney-ureter function." To the successful proven cases we add Case 1 and as further proof of the well-known fact that the absence of symptoms following the repair of a ureter does not prove the result satisfactory, we cite Case 2 in which complete healing with occlusion occurred after the removal of an undraining

Fig. 7 Bilateral ureterograms (retrograde reversed). Catheters could not be passed to kidneys as one ureter was completely occluded and the other was nearly occluded at the point of injury. Case 5.

catheter which permitted free drainage from the kidney for 15 days after the operation.

CONCLUSIONS

1. Normal kidney-ureter function may be obtained following complete severance of a ureter by end-to-end anastomosis over a ureteral catheter.
2. Simple ligation of a severed ureter is contraindicated if the condition of the patient will permit a conservative operation.
3. The absence of symptoms following the repair of a severed ureter does not prove the result satisfactory.
4. In old injuries of the ureter a suitable procedure must be adopted to each case. Reimplantation into the bladder is desirable if possible. Implantation into the bowel, nephroureterostomy or nephrectomy may be indicated.

THE PROGNOSIS OF THYROID CANCER

HOWARD M. CLUTE, B.Sc. M.D. F.A.C.S. AND SHIELDS WARREN M.D. BOSTON, MASSACHUSETTS

IT is generally recognized by all students of thyroid cancer that considerable confusion exists because of a terminology which varies with each author and because of different interpretations of the histology. We believe that in the last analysis histological studies of thyroid cancer are of value only as they benefit the clinical management of thyroid cancer cases. Attempts to associate certain histological pictures with more or less precise clinical findings have been made by pathologists since the days of Virchow. Such studies have proved of definite value in the clinical management of cases of buccal malignancy, bladder malignancy, bone malignancy, and so forth. It is logical to apply these methods to a study of cancer in the thyroid and we believe that by this method very definite help is provided to the clinician.

It has long been apparent to clinicians that certain types of malignancy in the thyroid were relatively benign, slow growing, and more or less amenable to treatment. It has been equally apparent that other cases of thyroid malignancy were extremely rapid in their course and entirely uninfluenced by treatment. It is our experience that these clinical types are characterized in general, by very definite histological anatomy and that the clinical grades of thyroid malignancy fall readily and easily into corresponding histological classes.

Our studies of thyroid malignancy first correlated these findings in 1929 (2) but in 1931 (3) the present method of grouping thyroid malignancy both from the clinical and the histological findings was emphasized. Increasing experience in the method that we discussed in 1931 has demonstrated to us its distinct value. We have repeatedly been able to predict the histology of certain thyroid cancers from our clinical observation of the patient before operation and we have usually been correct in our clinical prognosis of thyroid patients once the histology of the cancer had been presented to us by the pathologist.

We divide thyroid cancer into three clinical groups. In group I we have the patient with low or potential malignancy. In group II we have the patient with definite but not hopeless malignancy, and in group III we have the patient with severe and usually incurable malignancy. Patients can be placed in these clinical groups on

the histology of their tumors. Only by this combined histological and clinical grouping can an adequate prognosis be given and a constant background for comparison of results be obtained.

MATERIAL FOR STUDY IN THIS PAPER

In this review there are included 226 cases of cancer of the thyroid in which we have histological sections for study. The great majority of these patients have been operated upon, but in a few of the cases only autopsy material is available. These 226 cases have been seen in the Lahey Clinic up to January 1, 1932. None of the cases occurring in the Clinic during 1932-1933 or 1934 has been included.

Up to January 1932 there have been 18 additional inoperable cases of cancer of the thyroid in the Clinic which are not included in this study. Since no tissue was available in these cases they could not be classified histologically. All 18 are now dead.

Many of these 226 cases of cancer of the thyroid have been previously studied and reported upon. Thus in 1929 Clute and Smith (2) reported 67 cases of malignancy seen in the Lahey Clinic and in 1931 we (3) made a further study of all thyroid malignancy in the Clinic including those previously reported. The present study includes the cases reported in these two previous papers and such new cases as have occurred in the Clinic up to January 1, 1932 (Chart 1).

A constant follow up of all cancers of the thyroid seen in the Clinic is maintained. In the group I cases, the least malignant type, only 6 were completely lost. In groups II and III no cases were lost. We have therefore, a 97 per cent follow up on the 226 cases of thyroid cancer reported in this paper.

The papers on thyroid malignancy by Wilson, Graham, Pemberton, Wegelin, and Haagensen have well summarized the older literature as well as presented important new facts. It is unnecessary to review again the literature on this subject which these writers have covered.

CENTRAL CONSIDERATION OF CANCER OF THE THYROID

Symptoms. The classical symptoms so called of cancer of the thyroid are really those of the end stages of thyroid malignancy. A rapidly growing goiter with irregular lobulation distort

Fig 1 Fetal adenoma with blood vessel in axon, malignant No 4858 X 50

ing the usual symmetrical shape of the thyroid gland is rarely present until the condition is hopeless. Hoarseness, stridor, choking, inability to swallow, all appear late in the disease as invasion of the larynx, laryngeal nerves, trachea and esophagus take place. While we must state these symptoms and recognize that they arise in the final stages of this disease, it is much more important to be familiar with the earliest findings suggestive of thyroid cancer.

Fig 2 Papillary cystadenoma, malignant No 067 X 5

Fig 3 Adenocarcinoma, papillary type No 576 X 5

In the early stages of thyroid malignancy just as in the earliest stages of cancer of the breast, there are no symptoms which are positive and diagnostic. The significant and suggestive findings, however, which point to the possibility of cancer in the thyroid are the slow growth of as

Fig 4 Adenocarcinoma, alveolar type No 3526 X 165

Fig 6 Carcinoma of Hurtle cell type No 21145 $\times 400$

adenoma over a period of weeks or months. Increasing firmness of the tumor and the occurrence of a sense of pressure in the neck with lack of freedom of its movement on palpation is also seen in relatively early stages.

Clinically we must differentiate thyroid tumors suspected of malignancy from cases of chronic thyroiditis of the Riedel's type and the Hashimoto type from cases of acute thyroiditis and from cases in which there has been a sudden hemorrhage into a benign adenoma.

Riedel's struma is perhaps as frequently mistaken for cancer of the thyroid as any thyroid swelling. Not infrequently the final differentiation of this tumor is made only by histological study of sections. In general, however Riedel's struma is diffusely and usually bilaterally of a stony hardness but the enlargement of the thyroid is symmetrical. There are as a rule, no nodules and the superior poles and inferior poles on each side can be felt to be much like those of a normal gland though enlarged. There is rarely fixation of the tissues in the neck in spite of the

hard thyroid tumor nor is there evidence of recurrent laryngeal paralysis. Local tenderness is often noted in Riedel's struma.

In Hashimoto's thyroiditis or struma lymphomatosa we have a rare type of firm thyroid enlargement which like Riedel's struma is apparently of an inflammatory nature but which is marked by a diffuse lymphoid infiltration of the thyroid and by a definite enlargement of the entire thyroid. Here also, there is no diffuse involvement of the tissues of the neck the enlargement maintains the usual contour of the thyroid gland but is firm and hard and very frequently is considered to be a case of chronic thyroiditis. Here the correct diagnosis is generally impossible until histological studies are made.

In acute thyroiditis the history is usually very suggestive of the type of lesion. In most cases a preceding respiratory tract infection has occurred. Within a few days or weeks a tender enlargement of one or both lobes of the thyroid gland appears. On palpation the thyroid is found to be symmetrically or unilaterally enlarged. The enlargement, however retains the general contour of the gland. There is very marked and definite

Fig 7 Carcinom simplex, compact type N 22977
X 70

local tenderness. Often there is a low fever and occasionally evidences of hyperthyroidism of mild degree are present.

Hæmorrhage into a thyroid adenoma may produce a most confusing picture. The history however in most cases gives the correct diagnosis. The patients may or may not have previously noted a goiter. Suddenly, as a rule following exertion the adenoma of the thyroid increases definitely in size. This swelling occurs in the matter of a few hours or a day and is associated with marked local tenderness and at times with symptoms of choking and pressure in the neck. The tumor following hæmorrhage, tends to subside slowly over a period of days or a few weeks. Such a history differentiates at once the firm hard swelling which is present on examination in these cases as due to a recent hæmorrhage and not to malignant degeneration. Malignant degeneration of an adenoma though it may be rapid, is never a condition developing within a matter of hours or 1 or 2 days.

Fig 8 Carcinoma simplex, diffuse type N 18914
X 225

Thyroid malignancy is suspected then, because of a firm hard discrete type of tumor in the thyroid gland because of recent growth, either slow or rapid and because of secondary evidences of pressure such as difficulty in swallowing and breathing and hoarseness. Thyroid malignancy soon leaves the normal contour of the thyroid gland to grow in an irregular and unrestrained manner and to become adherent to adjacent structures. In a few cases, the presence of enlarged lymph nodes near the goiter is suggestive of the presence of malignancy. In rare cases bone metastases may be the first indication of the presence of malignancy in an apparently benign adenoma.

Sex. In 226 cases here studied 198 were females and 28 males, an incidence of 7 females to 1 male. The incidence of thyroid disease is in general much greater in women than in men. During the past 5 years, 4,779 patients were operated upon for goiter. Of these 648 were men—an incidence of 7 females to 1 male for all thyroid disease. The similarity in these figures is impressive and may indicate the common origin of cancer in previously diseased thyroids.

Age. Cancer of the thyroid while appearing most commonly in middle life may nevertheless appear at any age (Chart 2). The youngest patient in the series was 9 years of age. Increasing experience with thyroid malignancy has demonstrated to us the great fallacy of thinking that youthfulness of the patient precludes the presence of cancer of the thyroid. Of our patients 8 were 20 years of age or less, and 2 of these have died of cancer 1 aged 9 and 1 aged 13. Furthermore it is to be noted from the chart that 39 of our patients (or 16 per cent) were less than 31 years of age and 77 or more than one-third of all our patients were less than 41 years of age.

Fig. 9 Giant cell carcinoma No. 11245 X365

The age distribution chart shows that there is a preponderance of group I thyroid tumors in the age of greatest sex activity the great majority of these patients being 20 to 50 years of age (Chart 3). No such marked association with the active reproductive period is noted in the more malignant tumors of group II or group III which in fact tend to be more common after middle life (Charts 4 and 5).

Previous goiter. It has been stated by different writers on cancer of the thyroid that an adenoma of the thyroid or an adenomatous goiter preceded the malignancy in 90 per cent or more of all cases of thyroid cancer. We have attempted to obtain accurate figures as to the presence of a pre-existing goiter in our group of cases. Such figures however are open to a certain amount of question because of fallacious observations by patients. In many cases, however the pathology of the gland establishes the presence of an antecedent adenoma. We may generalize from this series and say that a goiter was almost invariably present for an appreciable time before operation in the patients of groups I and II. In group III however we find that often no goiter was noted longer than a few weeks or months before operation.

Cancer may occur coincidentally with exophthalmic goiter. We have in our records 4 cases of exophthalmic goiter and coincident malignancy of the thyroid gland (1). In these cases it is our belief that the malignancy occurred in a coincident adenoma in the hyperplastic gland but that the hyperthyroidism was related only to the presence of hyperplasia in the otherwise normal thyroid tissue.

Fig. 10 Fibrosarcoma No. 18794 X225

We have no evidence that hyperthyroidism arises as a result of the activity of malignant thyroid tissue itself. There is however evidence that some thyroid malignancies have secretory power. The classical example of function is afforded by Eiselsberg who reported the development of hypothyroidism in a woman after complete excision of an adenomatous thyroid gland. With the development of a large nodule in the sternum the hypothyroid symptoms disappeared but on removal of the sternal nodule which proved to be a metastatic adenocarcinoma of the thyroid she again became hypothyroid. The presence of active principle in the tissue of struma ovarii has also been well established.

GROUP I. LOW OR POTENTIAL MALIGNANCY

Group I is divided pathologically into 2 classes (1) adenoma with blood vessel invasion and (2) malignant papillary adenocarcinoma. We place first the adenoma with evidence of blood vessel invasion (7). The adenoma is of usually undifferentiated type either embryonal consisting of simple stalks of thyroid cells without evidence of alveolar formation usually arranged in a loose oedematous stroma or fetal with numerous small follicles, often showing no colloid with some cords or stalks of undifferentiated epithelial cells (Fig. 1). The stroma in these is also frequently abundant and oedematous with thin walled vessels, so just what we can regard as significant blood vessel invasion is uncertain. In 114 adenomata examined by Warren 31 per cent showed varying degrees of invasion of blood vessels and 10 per cent of these died of metastases. Adenomata in which fully developed carcinoma is present are not included in this group, but are classified under the appropriate type of carcinoma.

Fig. 11. Artist's drawing of autopsy specimen. Patient aged 60. Gouty 30 months—histologically adenocarcinoma of the thyroid with blood vessel invasion. Note the growth of tumor tissue through the subclavian and innominate veins into the superior vena cava. A similar case was previously reported in 1939 from this Clinic (Reference V.)

When grossly demonstrable invasion of vessels is present there is no question as to the malignancy of the tumor. In the group in which there is microscopic evidence of invasion only there is a 95 per cent chance that the tumor is not actually malignant. However the appearance of the 5 per cent which metastasize and kill and the 95 per cent which do not is identical. Thus the only safe course is to regard all relatively undifferentiated adenomata showing any evidence of blood vessel invasion as potentially malignant, and those showing gross evidence of blood vessel invasion as definitely malignant. Rarely in this type of tumor is it the metastasis, particularly the

metastasis to bone, that first calls attention to the existence of a thyroid adenoma with blood vessel invasion. We have never seen an adenoma metastasize or recur locally without evidence of blood vessel invasion.

It is important in searching for evidence of blood vessel invasion not to be misled by bits of thyroid tissue adventitiously caught in the vessels during the preparation of the sections. Definite evidence of invasion of the vessel wall and of intravascular proliferation is essential. Invasion of the capsule may or may not accompany vascular invasion. Haagensen, in his recent discussion of radiosensitivity of thyroid malignancy does

Chart 1. Tabulation of cases in this study showing division into three groups and the relative mortality of these groups

not speak of this type of tumor as a separate entity

We regard papillary adenocystomata as malignant if they show evidence of capsule blood vessel or lymph vessel involvement. Inasmuch as the excellent study by Montz carefully distinguishes the various recognized types of papillary tumors of the thyroid, we will not attempt to summarize the various forms of tumors of papillary type which may be encountered but will describe here only that type included in this particular group

The tumor is cystic, grossly capsulated, sometimes with gross evidence of ingrowth into veins. Origin from aberrant thyroid tissue is not infrequent. At times the origin of the tumor may be multiple although it is very difficult to distinguish between multiple origin and lymph node metastases. On section contents of the cyst are usually fairly scanty, sometimes serous, and more often blood tinged. Rarely, evidence of calcification is present in some of the papillae. Under the microscope we see usually a fairly dense fibrous capsule often invaded in one or more places by ingrowth of tumor tissue, and a tracery of branching papillae usually with a fairly obvious stromal cord carrying an abundant blood supply and lined with a single layer of epithelium ranging from cuboidal to high columnar (Fig 2). Nuclei are not placed uniformly toward the base of cell

as in the case of the more delicate papillary projections seen in the follicles in thyroid hyperplasia, but they may occur in almost any position in the cell, often occupying the center. Mitotic figures vary in their frequency although usually on prolonged search some can be found. These however, are of but little avail as distinguishing the lesion from the epithelial changes of hyperplasia inasmuch as here also mitotic figures may be encountered in the epithelium. We regard invasion of the capsule, invasion of the blood vessels or of lymph channels as being requisite for the determination of malignancy in this type of tumor

The marked radiosensitivity of this type of tumor is to be expected because of its papillary character. This is a feature usually associated with a good response to radiation in whatever organ the tumor may arise.

The clinical history of the group I patients is at times suggestive of the lesion which is found on histological examination. A goiter had been present in certainly 90 per cent of these patients for months or years before they came to operation, and as a rule the adenoma had shown no rapid change in size. The patients, however, not infrequently state that it had slowly become larger over a period of months or years. This growth should arouse the suspicion of possible malignant degeneration

Chart 2. Age distribution of cancers of the thyroid with fatalities of each age decade

On examination the majority of patients show a discrete adenoma of the thyroid which is often slightly firm but usually is freely movable. Occasionally the adenoma feels quite hard and this strongly suggests malignant degeneration. In a few cases the process has advanced to such a degree that the tumor is large and firm and hard, diffusely attached to the overlying tissues and obviously malignant. This finding however is a very unusual one among those cases which are classified under group I.

On clinical examination it is occasionally possible to decide whether the tumor is an adenoma with blood vessel invasion or a papillary adenocystoma. If several nodules are felt along the course of the jugular above the tumor they suggest very strongly that a papillary adenocystoma is to be suspected.

Of the 99 patients having adenoma with blood vessel invasion, 85 are followed to date. 8 others were followed for over 3 years before they were lost, and 6 could not be traced. Three patients in the 99 are known to have died of cancer of the thyroid, and 1 patient is still alive with a large recurrence present in the neck. Three others have died of causes unrelated to their goiter. Of the 99 patients 86 are well and free from cancer of the thyroid.

Chart 3. Age incidence of group I cases of thyroid cancer. Note the large numbers in this group occurring in early adult life.

Of the patients having adenoma with blood vessel invasion 89 were females and 10 were males. The age distribution for the cases with adenoma with blood vessel invasion follows closely the age distribution for all the cases in group I as shown in the chart.

The cause of death in 3 patients with adenoma with blood vessel invasion in each instance was local recurrence of the growth with metastases into the mediastinum and into the lungs. In 2 patients death occurred 5 years after the operation, and in the third patient within 1 year. In all 3 patients, however, it was evident for over 3 years that cancer of the thyroid with extensive invasion was present before death occurred.

Of the 51 patients with papillary adenocystoma, all save 1 were followed to date, and the 1 patient when lost was known to have been well 3 years after operation. Of these 51 patients, 36 are well with no evidence of malignancy and 8 have died of non-related causes. Four patients have died with local recurrences of whom 1 also had a metastasis in the brain. Two other patients in the group have large recurrences present now in the neck which are apparently quiescent under X-ray treatment.

Nine of the papillary adenocystoma patients were males and 42 were females—about 1:5. The age distribution follows that of the group there having been 1 case (fatal) in a boy of 9 and 6 cases in the sixth decade.

The deaths and recurrences in the papillary adenocystoma cases resemble in their clinical history very much the deaths occurring in patients

Chart 4. Age incidence of group II cases which tend to be increasingly common in middle age

Chart 5. Age incidence of group III cases which like group II occur most frequently at middle and old age.

having adenoma with blood vessel invasion. There were 4 deaths in the patients with papillary adenocystoma from cancer of the thyroid. All of these patients showed local recurrence with slow extension into the surrounding tissue. Two of these patients were inoperable when first seen yet following biopsy and X ray treatment lived 3 years and the other 1 year.

Two of the patients in the group have definite recurrences in the neck with extension into the mediastinum and into regional lymph nodes, one of which has been present, although held quiescent with X ray for 3 years, and the other for 4 years. One of the patients with the persistent recurrence was inoperable at the first operation and only a biopsy was done. Following a year of X ray treatment however it was possible to remove a large proportion of the tumor and 4 years after this, he was still well though nodules were present in his neck.

Our follow up studies, then of these 150 patients of group I type are complete for 135 or 90 per cent. Nine were lost after having been followed and found well for 3 years. Of the 144 cases 7 or 5 per cent, had died as a result of cancer of the thyroid and 3 others had definite recurrences. This means that 10, or 7 per cent, of the 144 patients followed in group I were dead or had recurrences from cancer of the thyroid. In our previous study in 1931 the mortality of group I cases was 4.5 per cent and it is gratifying to note that as several more years have passed in this group of patients, on further follow up, there is no tendency to increase the mortality from thyroid cancer recurrence. All recurrences or metastases in this group have occurred within a year after operation.

While a great many of the patients in group I have had X ray treatment as a routine for the first year following their operation, there have, nevertheless been many other patients who have

had no X ray treatment. It is not apparent to us, therefore, that failure to have recurrence following the removal of the group I type of cancer is due to the use of X ray treatment. There is no doubt, however that tumors in group I are quite susceptible to X ray treatment since we have in several cases seen inoperable tumors shrink to such proportion that their radical removal was possible after X ray treatment. It is also our experience with the recurrent cases that extension of the growth has been markedly slowed and limited by persistent X ray treatment after operation.

In all group I patients, recurrence tends to take place along the veins of the neck following the course of the blood stream toward the heart. Nodules therefore, appear in the mediastinum and in the lung. Local extension by penetration of the capsule by the growth also appears as a rule within a few months after operation if recurrence is to appear. Metastasis of the papillary adenocystoma frequently occurs by the lymphatic stream with involvement of the regional lymph nodes.

For the group I patients then, we may state first, that all of the patients dying from cancer of the thyroid of the group I type have been patients with clinically obvious cancer of the thyroid which was far advanced at the time of the original operation, and had been present for months or years before operation. All of the patients with local recurrences had extensive growths at their first operation and recurrences were apparent within a year after operation. Only the clinical findings indicate the prognosis in these cases since the histology is alike in all. Finally, in none of the patients that we have followed in this group has any recurrence appeared when the patient was well to clinical and X ray examination a year or more after the original removal of the thyroid tumor.

GROUP II ADENOCARCINOMA OF THE THYROID

In group II we place all cases of adenocarcinoma of the thyroid. Here although the lesion is unquestionably malignant there is some hope of cure and much chance of long relief and palliation by active treatment. In these tumors the usually accepted criteria of malignancy and plasma and invasion of surrounding tissue are obvious, but the degree of preservation of glandular structure varies considerably. In all of the tumors of this group however we expect to find some evidence of glandular structure and alveolar formation. Histologically the group may be readily divided into two forms, the papillary adenocarcinoma and the non papillary or alveolar.

The papillary form of adenocarcinoma differs from the malignant papillary cystadenoma of group I, by having more than one layer of epithelium over many of the papillary projections (Fig 3). There is a greater variation of size and shape in the epithelial cells and a definitely greater extent of invasion, not only of the capsule which is often indistinct or non-existent, but of the surrounding thyroid tissue and muscle as well. Mitotic figures are usually fairly frequent in the cells and tumor giant cells are occasionally encountered. In this type of cancer distant metastasis is rarely seen but regional lymph nodes are frequently involved whether by direct extension or by lymphatic metastasis is uncertain.

The alveolar type of adenocarcinoma, as has been brought out by Haagensen and others, presents a fairly wide variety of histological types. These range from forms resembling the more anaplastic of the adenomata (corresponding to the *wuchernde Struma* of Langhans) with predominant alveolar arrangement and not infrequent colloid-containing follicles, to tumors made up of cells barely recognizable as of thyroid origin with, however some maintenance of alveolar structure (Fig 4). Even in the less differentiated forms, however we can distinguish them from adenomata with blood vessel invasion by the slight or absent evidence of encapsulation, by the free invasion of surrounding structures, whether thyroid itself or muscle and by a distinct degree of anaplasia of the cells, many of which are small hyperchromatic, and ill-defined. In practically all the carcinomata of this group evidence of either blood vessel or lymphatic invasion can be found, if search is made. So far as we can judge from illustrations some of the tumors included in the *wuchernde Struma* we place in the group of adenoma with blood vessel invasion rather than in the group at present under discussion.

One special, though rarely occurring, variety of the adenocarcinoma is the so called Hurthle cell carcinoma (Fig 6). We have had but one clear cut example of this type although portions of some of our other adenocarcinomata have shown large clear acidophilic cells of the sort considered to be characteristic. The similarity between these cells and certain of the changes in thyroid cells most frequently encountered in involutions following primary hyperplasia led us to follow Ewing and others in considering this tumor as a true thyroid carcinoma rather than as of parathyroid origin as suggested by Eisenberg and others. While admittedly the cells resemble the oxyphil cells of the parathyroid, they appear to us to resemble even more closely the acidophilic phase occasionally encountered in the thyroid epithelium itself.

Because of the diverse character of this group it is rather difficult to lay down any general statement as to its probable behavior in regard to metastasis. Undoubtedly it would be desirable to separate the extremes of the group but when the adenocarcinomata are assembled they grade so imperceptibly from one to another that any establishment of a dividing line would be purely arbitrary.

CLINICAL COURSE OF GROUP II CASES

The typical clinical findings in the group II patients are in many respects similar to those present in the group I cases with the exception that the course of the disease is more obviously rapid, more definitely malignant, and more clearly serious.

The usual history of the patient with adenocarcinoma of the thyroid is that a goiter has been present for many years but within a short time perhaps 6 to 8 weeks, definite and obvious growth of the tumor has occurred. The patient frequently notes pressure symptoms as the tumor enlarges. These may be choking attacks or simple sensations of fullness in the neck. Hoarseness may occur early in these cases if the tumor lies near the recurrent laryngeal nerve.

On examination the usual finding is a discrete adenoma of the thyroid which is hard and firm and may be fixed to the surrounding tissue. It gives the examining finger the definite sensation of malignant tissue localized in a small area. In the more unusual cases the lesion is frankly an extensive malignancy obviously inoperable with wide involvement of all the tissue in the neck.

Three of the patients of group II were males and 28 were females—19. Adenocarcinoma is most commonly a disease of middle and late

life as is seen from the chart. It is important to note, however, that examples of this type of tumor may be seen in youth.

In the group II cases there were 31 patients all of whom have been followed to date. Seventeen have died of cancer of the thyroid while 4 others show definite evidence of recurrence. In other words, 54.8 per cent of the patients in this group have died of cancer of the thyroid and 68 per cent have died or have a recurrence of the disease. Ten are alive and well with no evidence of trouble.

In 9 or over half of the 17 fatal cases in group II minor operations such as biopsies alone or tracheotomies or decompressions of the prethyroid muscles were done at the time of operation and death occurred within days or weeks of this procedure. In 3 of the 8 remaining cases, radical removal of the obviously malignant tumor was followed by rapid recurrence and death. In 5 of the patients, however, radical operation plus X ray treatment seemed definitely to delay the fatal results death not occurring until some 2 to 5 years later.

Recurrences in these fatal cases were noted most commonly along the jugular vein and in the superior mediastinum (Fig 11). Metastases to the lungs were frequent. In 1 patient metastasis was apparently found in the pancreas at an abdominal operation 2 years after the removal of the adenocarcinoma from the thyroid. At this time no evidence of local recurrence was noted but sections from the pancreas were consistent with adenocarcinoma of the thyroid.

Four of the patients in group II are still alive with definite recurrences of their malignancy. In all 4 examination of the neck shows large hard firm, fixed masses extending downward into the superior mediastinum. In 2 of these patients X rays of the chest show definite metastatic nodules present in the lungs. All of these patients have had intensive X ray treatment, and their recurrences have been known to be present for 6 years, 5 years, 4 years and 3 years, respectively. In 3 other patients, recurrent nodules which had become localized and more or less discrete following long X ray treatment have been removed at second operations. In all of these patients however further recurrences have been noted following this secondary removal.

The 10 patients who are well have gone from 3 to 9 years with no evidence of difficulty.

When we reported on cancer of the thyroid in 1931 we found that the mortality in group II for the adenocarcinoma cases was 23.9 per cent. With longer follow up of these same patients and others of this group however we note that the

mortality now is more than double 54.8 per cent. It seems very clear that adenocarcinoma of the thyroid is a relatively slowly growing tumor nevertheless a most serious one since recurrences and deaths from cancer occur years after an apparently successful removal of the growth.

It is apparent that X ray treatment has a very salutary effect upon these adenocarcinomata and we believe that it has added to the longevity of patients who had obvious recurrences of the tumor. Furthermore, in other cases, inoperable tumors have become operable after intensive X ray treatment. It is not apparent, however, that the further removal of these collections of malignant tissue that have become more discrete following X ray treatment has been followed by any cure of the disease. As time goes on in these patients brawny induration and thickening of the neck with deeply placed malignant nodules have always been present. Haagensen reports a 71 per cent primary regression with radiation in cases of group II and a mortality of 57 per cent.

GROUP III HOPELESS MALIGNANCY

We include in group III the most highly malignant tumors. These we have subdivided into 4 classes the squamous cell or epidermoid carcinoma the carcinoma simplex or small cell carcinoma with evidence of alveolar formation which may be either compact or diffuse the giant cell carcinoma, often called carcinosarcoma or giant cell sarcoma and the fibrosarcoma, which is extremely rare. We do not include in the group the lymphosarcomata. We have yet to see a lymphosarcoma giving clear cut evidence of primary origin within the thyroid in spite of the frequency with which lymphoid infiltration of this organ is seen. In general we believe most of the so called primary lymphosarcomata of the thyroid to be small cell carcinomata of the diffuse type. All the tumors of group III are characterized by marked anaplasia by frequent invasiveness by a considerable degree of mitotic activity and by relatively free metastasis.

Although the clinical course of the group III cases is decidedly uniform, the pathological anatomy is varied. In the class of the squamous or epidermoid type of carcinoma, our only case gave evidence of origin from the thyroid stalk and may represent development from an embryonic rest or possibly from metaplasia of persisting thyroglossal duct epithelium. The presence of definitely keratinized cell membrane intercellular bridges and frequent formation of epithelial pearls leaves no question as to the nature of this tumor (Fig 5).

The second type of tumor in group III the small cell carcinoma or the carcinoma simplex, shows no evidence of alveolar formation, thus distinguishing it from tumors of group II. The type cell is often small polyhedral, and ill defined varying markedly in its relation to adjacent tumor cells and to the stroma (Fig. 7). Usually it has a large hyperchromatic, although occasionally vesicular nucleus. Mitotic figures vary a great deal, sometimes being very frequent and other times rather rare. Invasion of the surrounding tissues is always marked and blood vascular or lymphatic invasion practically always demonstrable. In the compact type of small cell cancer the epithelial cell masses occur in large or small clusters, closely approximated with one another with intervening bands of stroma. This structure is usually maintained in the metastases. In the diffuse type (Fig. 8) similar cells are scattered through the stroma either occurring singly or in clusters of 2, 3, or 4, as seen in the section. The cytoplasm is indistinct and ill defined, the nucleus prominent and hyperchromatic. Often the nucleus is practically all of the cell that can be seen. This coupled with the irregular scattering of the cells through the tissues, is undoubtedly strongly suggestive of lymphoblastoma. However we feel the nucleus to be distinctly of epithelial type and the tendency to clumping of the cells in some areas to be suggestive of carcinoma rather than lymphoblastoma. Metastases of this type of tumor are widespread and rarely have we seen a very definite epithelial type of growth in the metastases. As further aid in differentiating these tumors from lymphosarcoma the response to radiation is of value. In marked contrast to the radiosensitivity of tumors of the lymphoblastic series, this particular type of thyroid carcinoma is, in our experience, absolutely radio-resistant. Moreover in the lymph node metastases the epithelial character of the cells, and the manner of growth clearly distinguish the lesion from lymphoblastoma.

As to the specificity of type of the giant cell carcinoma of the thyroid there is no question. Here again, however there is dispute as to the exact nature of the tumor cells. We regard them as epithelial. This point was clearly demonstrated recently by Smith. This tumor often presents one of the most bizarre pictures encountered in oncology. Almost every conceivable size and shape of cells with marked variation of nuclear structure are seen (Fig. 9). Mitoses are frequently present and often are atypical to a startling degree. There is a strong tendency for rather plump spindle cells to predominate, although at

times polyhedral cells grouped compactly or even in pseudo-alveolar form surrounded by stromal bands are the outstanding feature of the growth. We have not succeeded in demonstrating fibroglia fibrils in relation to any of the spindle cells of this group.

In the last type, the fibrosarcoma, we have three examples. These are apparently perfectly typical fibrosarcomata. Their cells form both fibroglia fibrils and collagen and tend to be fairly uniform, elongated spindle cells arranged in strands, with an elongated nucleus of a somewhat vesicular type (Fig. 10). The character of the cells is fairly uniform throughout the tumor and only by its definite origin in the thyroid could it be differentiated from a typical fibrosarcoma of soft parts.

CLINICAL COURSE OF GROUP III CASES

The typical history in a group III cancer of the thyroid is often sufficient to give a definite suggestion of the type of lesion which is present. In most instances a goiter suddenly appears in middle or late life and rapidly increases in size. In some cases, a goiter has been present before attention was attracted to it by its rapid growth, but this is unusual.

Accompanying the growth of the tumor in the neck are pressure symptoms. These vary from a feeling of discomfort over the swelling with a sensation of pressure on swallowing to actual choking and dyspnea.

The rapidity with which group III tumors increase in size is often amazing. In many instances a tumor 10 centimeters in diameter is present a few weeks after the first small swelling appeared. This finding is especially common in the giant cell cancers.

On clinical examination the findings which the history suggests of a rapidly growing malignant tumor are usually confirmed. The mass is asymmetrically placed and it is firmly and widely attached to the thyroid gland. One readily gains the impression that the tumor has involved the whole lobe of the thyroid and is not just attached to it or growing in it. Very often the tumor is adherent to the structures overlying the thyroid gland and therefore, can be but slightly moved. Glands may at times be felt along the jugular vein and chest X rays may show metastases in the lungs at an early stage in the disease.

As will be seen from the chart, these patients are most frequently at middle life and beyond, regardless of the subtype of group III to which they may belong. All of the patients having small cell cancers were at middle life or over save

one boy of 13 and a woman of 25. All save two of the patients with giant cell cancer were 60 or more years of age and these two were 36 and 54 years, respectively. In the 45 patients in group III only 6 were males and curiously enough 5 of these 6 had small cell cancers while the other one had an epidermoid cancer. All the 11 giant cell cancers occurred in women.

There were 45 patients or 19 per cent of this series of 226 cancers of the thyroid who fall into our group III both by their histology and by their clinical behavior. All of these 45 patients were followed to date. Thirty six, or 80 per cent, have died of cancer of the thyroid. Three other patients now have serious recurrences so that 39, or 86 per cent of the group III cases are either dead or dying of cancer of the thyroid. In 1931, we reported the mortality of this group as 82 per cent. It would seem therefore that the same serious outlook prevails for these tumors with the treatment we have used.

It had been our plan up to January 1, 1934, to do as radical an operation as was possible in each of these cases and to follow this with X-ray treatment. Radium therapy has not been used in these cases up to January 1, 1934 but since that date we have added the use of radium to the operation and X-ray treatment. It is our plan to follow the results of this additional therapy closely and to report upon it at some future time.

In general X-ray therapy has been very disappointing in the group III cases. In most instances it has not affected the rapidity of the growth of the malignant tumor in spite of the relatively undifferentiated type of cells involved. In only 2 or 3 instances has it been apparent to us that X-ray treatment has checked or controlled the rate of growth. In only 1 case has an inoperable mass been reduced appreciably in size by X-ray treatment.

In 21 or nearly half of the cases in group III only palliative operative measures could be done. These consisted of biopsy only or biopsy plus decompression of the pretracheal muscles or tracheotomy. The very low operability of the group III cases is further evidence of the serious nature of the malignancy since many of them were seen within 2 months of the onset of the tumor.

The recurrences and metastases in the group III cases are seen early in the postoperative course. Local recurrence almost always is present and this tends to spread widely through the neck and into the mediastinum. In 1 patient, the growth spread in a few weeks from the neck into the right axilla. In another patient there was no evidence of any trouble for 4 years after operation

when multiple metastases appeared in the spine. In another case of small cell thyroid cancer retroperitoneal metastases occurred 4 years after the thyroid operation. Late metastases, however, are not common in group III cases. In most instances recurrences and metastases appear within a few weeks after operation and the course is rapidly fatal.

More than half of the deaths in the small round cell cancer cases occurred within 9 months of operation. There were, however, unexpected examples of longevity in some since 3 patients lived 3 years before dying of cancer and 6 lived over 1 year. Furthermore in 2 patients no recurrence appeared until 5 and 6 years after operation. Rapidity of growth and recurrence was especially notable in the giant cell cancers where the average length of life after operation in the 9 fatal cases was 4 months and the longest period 8 months. Similar rapidity of fatal endings occurred in the 3 fibrosarcomata and the 1 epidermoid cancer case.

The prognosis for the group as a whole appears to be hopeless with the therapy we have used. The few patients who in our previous studies appeared to be progressing favorably have developed late metastases and died. Of the 6 patients alive and well 2 had giant cell cancers 2 and 5 years ago. Four had small cell cancers and have lived 2, 4, 5, 10 years, respectively, since operation. This low survival rate graphically shows the serious prognosis of group III thyroid cancers and we believe that it is this particular group of cases that has given cancer of the thyroid its more or less justly deserved bad name.

SUMMARY AND CONCLUSIONS

1. Cases of thyroid cancer in their clinical course fall readily into one of three groups: group I, with low or potential malignancy; group II, with definite but not hopeless malignancy; and group III, with severe and usually incurable malignancy. Clear cut histological findings also mark out these clinical groups.

2. By this combined clinical and histological grouping of thyroid cancer an adequate method is at hand for estimating the prognosis in any case.

3. This paper reports the results in 226 cancers of the thyroid seen in the Lahey Clinic up to January 1, 1937. All but 6 have been followed.

4. The symptoms and diagnostic features of cancer of the thyroid in general are reviewed.

5. Group I cancers of the thyroid are those of low or potential malignancy. Histologically these patients have either adenoma with blood vessel invasion or papillary cystadenoma with blood

vessel or capsule invasion. Seven per cent of these patients are dead of thyroid cancer or have a recurrence. No death or recurrence has occurred in this group in any case free of trouble for a year after operation.

6. Group II cancers of the thyroid have clear cut, definite malignancy for which there is some hope of cure and much chance of long relief. Histologically all are adenocarcinomata of the thyroid. The mortality of the group however is 55 per cent, many fatalities having occurred from cancer years after the original operation.

7. Group III cancers are clinically the most hopeless type. Histologically this group contains the squamous cell cancers, the small cell cancers, the giant cell cancers and the fibrosarcomata. All these tumors are of rapid growth, occur most frequently in middle and later life and usually are rapidly fatal. The mortality of the group III cases is 80 per cent and most of the deaths in this group occur within a few months of the operation.

8. The treatment used in this series of 226 cases has been operation and X-ray radiation. Group I cases are highly sensitive to X-ray radiation. Group II tumors may regress consider-

ably under X-ray which in many cases may prolong life for years. Group III tumors show almost no improvement with X-ray radiation. Since January 1934, we have supplemented surgery and X-ray radiation with radium therapy in certain cases. This added measure of treatment will be the subject of a later report.

AN ASEPTIC URETERO-ENTEROSTOMY¹

EDGAR J. POTH, PH.D., M.D. SAN FRANCISCO, CALIFORNIA
Fellow in Medicine of the National Research Council

ALTHOUGH the Coffey-Mayo technique for the implantation of ureters into the bowel is frequently productive of good results clinically, it is fraught with the ever present danger of infection. The success of this procedure depends upon establishing a check valve in the distal course of the ureter. This is accomplished by imbedding the ureter between the muscularis and submucosa of the bowel for several centimeters just proximal to its ultimate opening into the colon through the submucosa and mucosa. By applying the principle of the check valve, Coffey succeeded in eliminating dilatation of the urinary tract by the intermittently elevated intraintestinal pressure.

To insure a properly functioning check valve, however, healing in the absence of infection must occur between the implanted segment of the ureter and the bowel. Only under such circumstances will a minimum of fibrosis and deposition of scar tissue result. A stiff indurated, non-flexible, intramural channel cannot be readily compressed by an increase of intraintestinal pressure and will not result in a correctly functioning check valve. Therefore, every permissible safeguard must be employed to prevent infection and secure perfect healing.

Fig. 1. First stage of operation. A, Ureter dissected out. Bed in bowel wall has been prepared near the mesenteric border and down to the submucosa. Blood vessels not disturbed. B, Posterior parietal peritoneum has been closed. Ureter imbedded, a Cushing stitch of plain No. 0 catgut being used. Note that the bed is not completely closed; submucosa shows at each end. C, Anterior view showing both ureters implanted without catheters. D, Cross section of C.

The operative technique for performing uretero-enterostomy to be described fulfills the following requirements: (1) complete surgical asepsis, (2) healing in a clean anastomotic bed, and (3) assurance of an opening between the ureter and bowel.

OPERATIVE TECHNIQUE

The operation is divided into two stages. The first stage is concerned with imbedding the intact and uninterrupted ureters in the wall of the bowel between the muscular layers and the submucosa. At the second stage the ureters are interrupted distally, openings are made between the ureters and the bowel, and the bladder is removed.

First stage of the operation. The first stage is readily followed in Figure 1. The ureters are dissected free for some 10 centimeters and the posterior parietal peritoneum is closed. The beds to receive the ureters are prepared in the same segment of bowel. Two incisions about 6 centimeters long extending longitudinally along the bowel approximately $1\frac{1}{2}$ centimeters on either side of the mesenteric attachment, are made through the serosa and longitudinal muscle fibers. The cut edges are separated by blunt dissection by means of the handle of the scalpel. Any remaining circular fibers are carefully divided without injury to the underlying vessels and submucosa. It is not necessary to place both implants in the same segment of the bowel, but since no damage is done to the blood vessels there is no contra-indication to doing so. In this experi-

Fig. 2. Glass shields and cutting element. The glass tubes are threaded with silk sutures having loops tied in the free ends. The loop will be hooked over the end of the cutting wire to facilitate hauling it through the glass shield. a and b, Stiff blunt drawing needles. c, is a length of "advance resistance" wire, No. 24 B & S gauge.

The "advance resistance" wire is a nickel-copper alloy wire manufactured by the Draper-Harris Co., Montclair, New Jersey. This wire is well adapted to the procedure mentioned because it is flexible, has sufficient tensile strength when hot, and does not become brittle after heating. The electric current is adjusted to give a low red heat, which is satisfactory cutting temperature.

Figure 3. Second stage of operation. Bladder removed. Proctoscope inserted. Needle *a* has been inserted into the ureter and up to a point determining the proximal end of the opening between the bowel and the urinary tract. *B* Shows needle *a* having been thrust through the visceral wall and grasped by an alligator clamp in the proctoscope from below.

mental work on dogs, all implants have been made at the same level without any evidence of circulatory embarrassment. A single continuous Cushing suture of plain No. 0 catgut is used to imbed the ureter, the sutures passing into the submucosa. Sufficient tissue is included in the suture to approximate about 3 millimeters of serosa on each side. It is important to leave submucosa of the bowel showing at each end of the bed for a distance of approximately $\frac{1}{4}$ centimeter (Fig. 1*B*). This prevents sharp kinking and compression of the ureters. Urine flows freely within 3 to 4 days and ureteral catheterization is unnecessary. No attempt is made to extraperitonealize the ureters distal to the implant. Omentum is placed over the implants without suturing, and the abdomen is closed.

Second stage of the operation. After 3 weeks the abdomen is reopened. The ureters distal to the unbedded segments are isolated, clamped, and divided at a convenient distance beyond their exit from the bowel wall. The bladder is removed, and the bladder neck cauterized with phenol and closed. At this point a proctoscope is introduced

Fig. 4. Second stage of operation. *A*, Half the length of the wire has been pulled through, a shield of glass tubing has been placed over the wire, and needle *a* has been clamped to prevent slipping. Needle *b* is inserted into the ureter with its point just inside the distal junction of ureter and bowel. *B*, Needle *b* has been thrust through the visceral wall and grasped in an alligator clamp.

into the rectum and inserted until the end is opposite the distal junction of the imbedded ureter with the bowel wall (Fig. 3). An opening is made into the lumen of the distal segment of ureter about 2 centimeters from its exit from the bowel wall, and needle *a* of the cutting element, illustrated in Figure 2, is inserted up to the level at which the opening between ureter and bowel is to be made (Fig. 3*A*). With the edge of the proctoscope acting as a fulcrum the needle is rotated forward so as to invert the bowel wall, buried ureter and needle into the open end of the proctoscope. This accomplishment is evident to the operator from the abdominal cavity and it is plainly visible from below through the procto-

catheter inserted into the ureter Note that the electric cord to the proctoscope light must be disconnected before the handle of the cautery is attached! B The opening has been made and the cutting element removed. By digital pressure on the wall of the bowel and distal end of the catheter the latter is forced

Fig 7 Operation completed A section has been removed to show more clearly the opening into the bowel.

scope. Needle a is now thrust through the visceral walls grasped with an alligator clamp in the proctoscope from below and drawn out until half the length of resistance wire is pulled through. One of the shields of glass tubing is slipped over the wire as illustrated in Figure 4. Needle b on the other end of the cutting wire is put into the ureter and pushed through the visceral walls just inside the distal junction of ureter and bowel (Fig 4A and B). This needle is picked up and drawn out of the end of the proctoscope. At this point care must be taken to avoid crossing the legs of the resistance wire which would result in an electric short circuit later. A shield of glass tubing is placed over this leg of the wire and, after the electrical cord to the proctoscope light has been disconnected both needles are attached to the cautery (Fig 5 1). The ureter is catheterized

as indicated. By this procedure urine will not pass over the hot wire and the urethral wall and bowel opposite to the cutting element will be protected by the interposed catheter. Gentle traction on the handle of the cautery pulls the visceral walls into the open end of the proctoscope (Fig 5A). The circuit is closed and the cauterization is completed in about 15 seconds, where upon the cutting instrument can be drawn from the proctoscope. The wire should be examined to determine that it is intact. Should it have broken a second cutting element can be introduced and the entire procedure repeated. However ordinary care will make this unnecessary.

The bowel wall overlying the opening is inverted into the proctoscope with digital pressure and the distal portion of the ureteral catheter is pushed in to project into the proctoscope as a

loop (Fig. 5B). The length of the cauterized opening is clearly visible from below. The catheter is removed through the proctoscope to obviate soiling of the operative field (Figs. 5B and 6A). The distal segment of ureter is divided closely against the bowel wall, the ureteral vessel ligated and the raw area covered by a single suture in the wall of the colon (Fig. 6B).

Immediately following the completion of this procedure on the one side it is repeated on the opposite ureter. There is practically no bleeding, and urine is seen to flow freely into the proctoscope.

RESULTS

Following the first stage, in which both ureters are imbedded simultaneously the blood urea is usually increased for 3 or 4 days corresponding to a temporary postoperative anuria. The animals drink and eat very little during this time. They then begin to drink and urinate freely and the blood urea returns to normal in the course of the next 2 days. Some of the animals eat, drink and urinate normally the day following operation and the blood urea is not increased during this postoperative period. None of the animals show any gross abnormalities. Intravenous urography reveals no dilatation of ureters or kidney pelvis. When the second stage of the operation is done some 3 weeks later there is no evidence of hydronephrosis or hydronephrosis. The kidneys are macroscopically and microscopically normal.

The establishment of the communication between ureter and bowel at the second operation is accomplished with a minimum of healing surfaces. The blood supply to the healing mucosal edges is unimpaired and so fibrosis must be minimal. Urine flows freely into the proctoscope as soon as the opening is made between the ureter and bowel. At no time has there been anuria during the second postoperative period. The urea content of the blood rises somewhat in the course of a few days and fluctuates from day to day apparently depending upon the amount of water and nitrogenous material reabsorbed from the bowel. Intravenous urography again reveals normal outlines of kidney pelvis and ureters.

SUMMARY

1. A new technique is described for uretero-enterostomy.
2. Complete surgical asepsis is maintained.
3. Healing between ureter and bowel in the absence of infection is insured.
4. A non fibrous, patent communication with a check valve control is established between ureter and large bowel.
5. Postoperative dilatation of the urinary tract has not occurred.

The author wishes to acknowledge the able assistance and helpful suggestions of Dr. H. E. Shiff, of the Peiping Union Medical College during the latter part of the investigation.

INFECTIONS OF THE HAND

IN spite of the contributions and teachings of Kanavel in Chicago of Auchincloss and his students in New York of Bunnell in San Francisco and of many other interested workers in many parts of the country the toll of time money and loss of function taken from the working man in particular as a result of infections of the hand is still far greater than it should be.

There are doubtless a number of factors responsible for this condition. One important one obviously is the lack of knowledge on the part of the public with reference to the proper treatment of open wounds. Too often the first thought that occurs to many an individual who has sustained an open wound of the fingers or hand is the confident assurance that has come to him over the radio only the day before that if he will only be modern, and apply listovapopepsogone solution liberally to the open wound the outcome will be all that could be desired. Nor can the medical profession claim complete immunity to the siren wiles of the purveyors of merchandise. One

need only recall the long list of 'ideal' antiseptics and of healing ointments, now almost forgotten to realize how credulous we have been in the past.

Another factor deserves still more thoughtful consideration. The care of infected hands is often relegated to the young and inexperienced surgeon. Particularly is this likely to be true in our large public institutions. The chiefs of the service cannot be bothered with the care of trivial conditions; they must center their attention on major surgery. The assistants take their cue from the chiefs; the contagion affects the residents in turn and the patient eventually finds himself in the hands of the inexperienced junior interne. Too often not until some ill advised incisions have been made and not until the pathological process has advanced to such a degree that it is obviously a matter of grave concern are the older members of the staff called in and the thoughtful attention that might have averted serious trouble if aroused earlier concentrated on controlling what has become a life threatening infection or on attempting to save the seriously injured structures so essential to normal function.

This condition reflects in turn an attitude which prevails in many medical schools. So much attention is devoted to thyroid surgery, surgery of the biliary tract, of the digestive tract, etc., and perhaps to the rare and dramatic surgical lesions that are engaging the attention of some member of the surgical department that little time is left for consideration of the more prosaic but surely much more important conditions resulting from wounds and infections. As a result, the student con-

fronted with such cases at the outset of his hospital career has no definite conception of the problem involved or how to meet it

A member of the surgical department of one of our large medical schools was asked recently whose duty it was to consider with the students the problems of infection and injury. After a moment's thought he replied "I don't believe there is anyone in our department who is particularly interested in minor surgery. As long as infections of the hand and in fact infected wounds of any part of the body are considered minor surgery we will not make much progress in the surgical care of patients with infection and injury."

It should hardly be necessary to repeat what every first year medical student knows, and what the senior student too often has completely forgotten, that the hand is a marvelous and intricate mechanism. When this delicate mechanism is entrusted to the care of the novice in surgery, armed with a sharp scalpel and an urge to "do things," the result is often unfortunate.

The remedy, I think, lies in our own hands. It involves

1. Greater emphasis in our surgical teaching upon basic surgical principles and more specifically upon accurate diagnosis and proper treatment in cases of infection and injury.

2. Proper emphasis on these problems in the hospital and delegation of the responsibility for their solution to the most experienced men on the staff. It is interesting and stimulating to read a plan for organization of the surgical service of the hospital so that the patient with a postoperative pulmonary embolus can be operated upon promptly and given a chance for life.¹ But from the standpoint of our obligation to the public, and of accomplishing the greatest good for the greatest number, is it not imperative that the sur-

gical service should be organized so that patients with infection and injury can receive prompt and truly skillful attention?

3. Education of the public to the fact that in the immediate treatment of injuries simple soap and water cleansing and protection of the open wound against infection from without, with the aid of a sterile dressing constitute the best possible form of first-aid treatment and one which is based on sound surgical principles.

STANLEY L. KOEN

JEJUNOSTOMY FOR RESTORING ELECTROLYTES LOST IN PERSISTENT VOMITING

IN the average instance, postoperative vomiting is readily combated by the well known routine of the indwelling stomach tube and the maintenance of water balance by administrations in the veins, under the skin and by rectum. The unusually prolonged and unyielding type of postoperative vomiting presents an entirely different problem. It is a question whether the surgical profession broadly speaking appreciates all of the factors concerned in a favorable or unfavorable response to treatment. In the work of the average surgeon a year rarely elapses without his experiencing one or more instances of excessive and prolonged postoperative vomiting and encountering therefrom an unexpected fatal outcome.

The usual story is that vomiting becomes excessive about the fifth day and that in spite of gastric decompression by indwelling tube and maintenance of fluid balance by administration of saline and glucose solutions in the veins the vomiting continues, thus resulting in a tremendous loss of gastric and intestinal juices. With this excessive vomiting the abdomen shows no distention (often remaining flat) and frequently reveals peristalsis in the lower coils. There are occasional bowel move-

¹Leventhal, H. Preliminary jejunostomy, the need of operation for prompt surgical intervention. *J. of the Am. Med. Assoc.* 1915, vol. 4, 234.

ments. The surgeon after futile search, can find no explanation of an obstructive character for the continued and excessive regurgitation. The patient continues to lose in circulatory strength blood volume, and suddenly in a few hours goes down hill rapidly to a fatal outcome. Evidently in these cases there is some type of mechanical block probably edema near or at the duodenojejunal junction. With obstruction at this point, vomiting immediately entails a total loss of all the digestive juices. Experimental work has definitely demonstrated that life is impossible without pancreatic juices, that with persistent vomiting not only is the pancreatic secretion lost but also the electrolytes (sodium and chloride ion) from the duodenal and gastric juices and in addition there is loss of the bile and other intestinal juices secreted by the mucous membranes. Some authorities contend that loss of the bile salts which activate the lipases and aid in the emulsification of fats in the intestines is more serious than the loss of sodium and chloride ion.

Rowntree has estimated that the secretion of digestive fluids averages from 5 to 7 liters daily. Thus in prolonged excessive vomiting not only is there a tremendous loss of water but more important there is the loss of the electrolytes and the hormones of the pancreatic secretion without which life is impossible. Surgeons generally are familiar with the invariably fatal outcome of prolonged duodenal fistula. This of course entails loss of pancreatic fluid and electrolytes with the resulting acidosis of the uncompensated type. Prolonged excessive vomiting not only results in a loss of bile, pancreatic and intestinal juices, electrolytes and tremendous quantities of water but finally winds up with definite alkalosis from loss of gastric acids. While it is generally conceded that death following this condition is due to dehydration it is more

important for us to remember that dehydration in turn is specifically dependent on the loss of electrolytes together with certain qualities of pancreatic secretion.

Wilkie called our attention to the fact that death in high obstruction is due to loss of all digestive secretions by vomiting. Clinically Brockman has reported remarkable relief from obstructive types of vomiting by the administration of bile in the vomitus by rectum. In the past few years a great many surgeons have adopted the principle of returning vomited digestive fluids back to the patient by rectum yet we must remember that absorption by rectum as compared to the jejunum represents a ratio of about one to four. The principle however should be utilized early in every case of postoperative vomiting. White and Fender demonstrated experimentally that death in animals in simple high obstruction could be prevented by returning the vomited material into the small intestine below the point of obstruction.

This very brief statement of relative facts concerning the fatal outcome in some cases of prolonged and excessive vomiting leads to the suggestion that death might be circumvented in many cases of duodenal fistula or unyielding excessive vomiting from simple duodenal obstruction by the institution, promptly, of a jejunostomy and the return of all vomited digestive juices into the jejunum. We have had the opportunity to observe the efficiency of this method on four occasions and consider that the maneuver of jejunostomy with return of all vomitus into the jejunum is definitely a life saving measure. The step is to do a jejunostomy and connect directly to the jejunostomy tube an indwelling nasal tube which has been passed into the stomach or duodenum. As a rule the drainage of the gastroduodenal juices readily run over through the stomach tube into the jejunal

tube. If there is vomiting with regurgitation around the indwelling stomach tube this should be immediately and totally returned with aid of a funnel through the jejunal tube. There has been no difficulty in the jejunum tolerating as much as one pint of vomitus returned at one time. The general influence on the patient for good is immediately noticeable. It is of course assumed that the electrolytes of sodium and chloride ion together with sufficient water will be administered by vein and under the skin. Often it happens that these routes have been more or less exhausted and the making of a jejunostomy with return of vomited digestive juices will become the determining factor between life and death. Especially consoling is the fact that the jejunostomy provides an avenue for administering water, hypertonic saline, and nourishment without further delay.

Recently a case of gangrenous pancreatitis showed every tendency toward recovery after surgical drainage until the tenth day when vomiting and excessive loss of digestive juices began and none of the usual routine measures would bring relief. Over the previous 10 days parenteral administration of saline solution, water and glucose had supported the patient and this method was now becoming intolerable and insufficient. The question of intestinal obstruction anywhere below the duodenojejunal junction was ruled out and with out further delay jejunostomy was promptly done and the indwelling gastroduodenal tube through the nose was immediately connected up with the jejunostomy tube. All drainage from the nasal tube and all regurgitant di-

gestive juices around the nasal tube were immediately returned to the jejunum. Water, hypertonic saline, and gradually nourishment was given through the jejunostomy tube. The patient's improvement was almost immediate and continued to final recovery. Another case of duodenal and biliary fistula showed immediate favorable response to the return of all the fistulous discharge together with fluids and nourishment to the patient through a jejunal tube.

Surgeons should remember in every case of postoperative vomiting that the loss of digestive juices has a serious effect on blood volume through a sacrifice not only of water but important electrolytes representing inorganic factors in the composition of digestive secretion. Loss of electrolytes means dehydration and dehydration means reduction of the volume of blood plasma and increase of concentration of plasma protein. These physical changes together with increase of viscosity and a rise in the red count must interfere with the function of the blood as evidenced by huge reduction of the oxygen content of venous blood in duodenal obstruction and finally in the development of a lethal alkalosis as proved by the high carbon dioxide combining factor.

The moral is that prolonged and excessive vomiting is often *per se* fatal that jejunostomy with gastric tube hook-up is simple and devoid of danger. Most important, in duodenal fistula or duodenal obstruction, jejunostomy should be done early for restoration of lost digestive fluids before lethal dehydration can take place. ROBERT LEE PAYNE.

L. L. McArthur

MEMOIRS

LEWIS LINN McARTHUR

IN the death of Dr. Lewis Linn McArthur the medical profession lost one of its most distinguished members and the surgical profession one of its leaders.

Dr. McArthur possessed qualities of mind and heart that are not often to be found in the same degree in one person and he had in unusual measure the confidence and respect of all who were associated with him and the love and appreciation of his friends. As a surgeon he never grew old but was interested and interesting to the end.

During the many years I knew Dr. McArthur I was impressed with his surgical acumen and his ability to adapt to the individual patient the surgical procedures to be carried out. He had a rare understanding of surgical pathology and what might be called a flexibility of operative technic. I have seen him in the middle of an operation on recognizing that the procedure he had planned was not best adapted to the case change from one method to another with complete success. He insisted that the tissues at operation be handled with extreme gentleness, and that meticulous care be exercised in all coaptations.

But more than technical skill he had a humane understanding of the emotional states from which the patient suffered. He appreciated the natural desire of the patient not only to feel well but to look well and he wanted to be of aid, in building up not only his physical but his mental condition. In his work he was a marked individualist. He took the most intense personal interest in each case, always visiting his surgical patients at least twice daily.

It would appear sometimes that the modern surgeon thinks of surgery only from the standpoint of the operation, the after-care of the patient and the physical results. He carries out with the most scrupulous attention the necessary technical procedures, but not always does he possess that kindly spirit of helpfulness which is essential to carry the patient through an operation, to instill the confidence and courage which so often bring the patient safely through a crisis he might not otherwise withstand.

Perhaps this characteristic of spiritual understanding comes to those who in their earlier years were successful general practitioners, that is, practicing not only surgery but medicine as related to surgery. Perhaps the ability not only to acquire the confidence of the patient, but to deserve it to see what the patient desires and

needs, comes through the sixth sense we call intuition which in turn comes from wide experience and deep sympathy for and devotion to the patient, giving to the possessor remarkable ability to achieve results.

Dr McArthur had a large surgical practice which took up his time to an extraordinary extent and he was a successful surgeon because his skill and his humanity enabled him to carry many patients through most serious operations. He was a general surgeon to the last but like all general surgeons of the older school the pressure of patients afflicted with certain types of disease compelled him to restrict his work to rather definite fields.

Among Dr McArthur's numerous contributions to surgical science those in which he felt the greatest pride were (1) the muscle splitting incision for approach to the appendix which is usually attributed to McBurney (among the papers found in his desk after his death was a letter dated 1894 from McBurney acknowledging Dr McArthur's priority) (2) the autoplasic fascial repair of inguinal hernias used in the McArthur clinic as standard since 1896 and recently popularized by Gallet (3) the supra-orbital approach to the pituitary (4) the use of the gall bladder or common duct for the administration of fluids (5) the buried catheter method of common duct and ureteral repair (6) the "tobacco pouch" method of nephropexy and (7) the method of rectosigmoidostomy for complete rectal prolapse.

The many scientific papers which Dr McArthur contributed to the various medical societies are a measure of his intense interest and activity in his profession. They are too well known to require discussion. Dr McArthur was a member of his county and state medical associations in Illinois of the Chicago Medical Society of which he was a past president of the Chicago Pathological Society the Chicago Gynecological Society the Institute of Medicine of Chicago the International Surgical Society the Colorado State Medical Association, the Western Surgical Association, the American Medical Association the American College of Surgeons, the Society of Clinical Surgery and the American Surgical Association of which he was president in 1922.

Lewis Linn McArthur was born January 23 1858 in Boston Massachusetts, the son of Major Joseph Hunter McArthur U S Army and Julia Woodworth McArthur daughter of Samuel Woodworth poet, who perhaps was best known through his well-known poem "The Old Oaken Bucket."

In 1878 Lewis L. McArthur matriculated at Rush Medical College and was graduated in 1880. He won first place in the competitive examination for internship at the Cook County Hospital where he served 2 years. On completion of his internship he spent 2 years in Vienna and Heidelberg in postgraduate study before returning to Chicago to take up his life work. He fitted out the first opeonic index laboratory in Chicago and sent his first assistant, the late Dr John Hollister to London for a year about 1900 to study there the method of Wright.

In 1917 he received the commission of Major in the Medical Reserve Corps of the U S Army and he organized and was director of U S Base Hospital No 14 He was made Chevalier of the Order of Leopold of Belgium in recognition of his service to Belgium during the war

Dr McArthur is survived by three sons Dr Selim W Lewis Linn Jr and Billings Meacher McArthur Dr Selim W McArthur was fortunate in receiving his surgical training under his father He has continued on the staff of the hospital where Dr McArthur did much of his life work and he well fulfills the tradition established by his father for skilled and humanitarian service W J Mayo

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

VOLUME X of the *Cyclopedia of Medicine* now appears and it covers the section *PRE to RUB*. The first subject covered is pregnancy, parturition and puerperium, and the first 30 pages are given to the anatomy of the female generative organs and the pelvis. The next 30 pages cover maternal care, so that a great amount of detail is given to each topic, the whole subject requiring 362 pages. The next section covers the anatomy, physiology and disorders of the prostate and the section on treatment is filled with fine illustrations and drawings. A large section of 600 pages is given to the phases of radiology. Remittent fever, "reticulo-endotheliosis," and "rhubarb" indicate the great spread of topics discussed. The whole volume of 1167 pages is well printed on good heavy paper and bound in a firm, green colored binding. Vols. X and XI conform nicely with the high caliber of the preceding volumes. Volume XI covers subjects occurring alphabetically between the letters *RIC* and *TEL*. Individual topics are contributed by men familiar with the subject so that the associate editors are found widely scattered. The first topic in Volume XI is that of *Rickets* written by Drs. Park, Ebot and Bromer. *Rickettsia*, rubella, saccharin, scarlet fever, silver skin grafting, social service, spinal cord disorders, spleen, sprue, staining methods, stomach including its surgery, strophanthus, syphilis, ending with tar and tartar indicate the scope of medicine, surgery, pharmacology and laboratory methods described. The volume consists of 1111 pages of well printed, well edited material in the conventional rigid binding.

The *Cyclopedia* is edited by Dr. George M. Piersol, and the review of the first seven volumes, which appeared in the December 1933 issue of *SURGERY, GYNECOLOGY AND OBSTETRICS* (p. 822) covers the detail of the plan. M. H. BARKER

STUDENTS and gynecologists alike will welcome this second edition of Curtis' *Textbook of Gynecology*. While adhering to his original idea of having the book reflect his own viewpoint and practice, he has lengthened it by some 107 pages, thoroughly revised the illustrations and increased its written material by about 70 per cent. This is a textbook

and, therefore, covers, as we would expect, all of the frequently encountered gynecological conditions—the infections, the neoplasms, the injuries of childbirth and displacements, and the functional disturbances. Its great value lies in the fact that it is the work of a master gynecologist who presents the subjects of gynecology to us with remarkable clearness, and, considering the size of the volume, with surprising thoroughness. Everywhere he has given us the results of his own rich clinical experience and laboratory investigations. In 4 years there has been naturally a slight shifting of his viewpoint on several subjects, a thing that may be sensed by those who are familiar with both editions. The feature that is perhaps of greatest interest is the chapter on "Internal Secretions." The author has condensed into a chapter about all that is really known about this intricate subject, and it is exceedingly clear and well done. He has at various points in the book sought to couple up this knowledge with the treatment of various disorders. He remarks "despite the meager progress in treatment we are justified in assuming that further developments are imminent. Moreover, dependable tests for early pregnancy, for death of the fetus *in utero*, and for determination of the postoperative cause of chorio-epithelioma merit inclusion in the list of advances made in the care of gynecological patients." RICHARD R. SMITH

A FITTING monument to the work of Dr. Wilmer who is retiring as chief of the Wilmer Institute of Johns Hopkins University is found in *Atlas Fundus Oculi*. The color plates of the fundus are by Annette Burgess, an artist trained by Dr. Wilmer especially for this work, and are made from his own patients and those of a few colleagues. They are beautifully reproduced, and represent a satisfactory variety of conditions seen with the ophthalmoscope. Only one criticism might be made of the illustrations as a whole—the light reflexes, the appearance of nerve fibers in the fundus and that of fine granular pigment appear in some cases to be exaggerated.

The careful description of the normal fundus and its common slight congenital abnormalities such as hyaloid remains on the disc is well done and of great practical value, since, as the author points out, it is common to see these mistaken for various conditions indicating disease. Thus the disc in high hyperopia

THE *CYCLOPEDIA OF MEDICINE*. George Martin Piersol, B.S. M.D. Editor-in-Chief, and Edward L. Borgia, A.B. M.D. Associate Editor. Vol. 10 and 11. Philadelphia: F. A. Davis Co. 1934.

A *TEXTBOOK OF GYNECOLOGY*. By Arthur Hale Curtis, M.D. ed. of Philadelphia and London: W. B. Saunders Co. 1934. First edition reviewed 1933, 51 178.

ATLAS *FUNDUS OCULI*. By Wilmer McLeod Wilmer, M.D. LL.D. Sc.D. Introduction by Warfield T. Lamphere, M.D. New York: The Macmillan Co. 1934.

is properly distinguished from that in early optic neuritis.

The findings in each case are briefly and simply described, with a minimum of discussion as to vexing questions of pathogenesis. Perhaps there is too little discussion of certain conditions. Thus colloid excrescences are described as such, and properly illustrated in Plate 86 yet it might have made the matter clearer to state that they are hyaline deposits on the lamina vitrea of the choroid and hence always very deep in the retina and seen through a certain of retinal tissue. His other illustration on Plate 84 of colloid excrescences seems to represent a somewhat different type of deposits which is located in the retina itself. The author's use of the term *druses*, an Americanization of the German *Drusen*, usually employed as synonymous for colloid excrescences, is here noted by the reviewer for the first time.

The fundus conditions observed in hypertension, arteriosclerosis, nephritis, and diabetes are beautifully illustrated, and brief summaries of physical and laboratory findings in the illustrative cases are included. Enough distinction is not made between conditions due to arteriosclerosis and the type of change called by Fishberg hypertensive neuro-retinopathy which distinction seems to be justified by recent additions to our knowledge of cardiovascular pathology. Especially valuable is the representation in several cases of the changes in individual lesions. A fine example is that illustrating the progress of a solitary tubercle of the choroid in Plates 39 to 41. The book will prove exceedingly useful to one studying ophthalmoscopy, as a reference book in any ophthalmologist's library and especially in institutions where ophthalmoscopy is being taught.

SAMFORD R. GIFFORD

FORMER editions of Jordan's well known student text¹ on histology have been reviewed in this journal. It is a useful student aid of the traditional type which furnishes reliable information on the more static features of tissue structure and organ architecture. Indeed the chief suggestion toward improvement might well be the adoption of a dynamic viewpoint throughout.

Each successive edition has shown some improvement although no radical departures have been made from the original plan, scope, treatment, or phraseology. The present (sixth) edition follows its predecessor closely except for a change in format. A larger page of more richly sized stock has been adopted, evidently to the end of improving the quality of the halftone reproductions. Slight gains for the better have been made in this direction. Any such advantage however is largely offset by the larger, thicker and heavier volume which has resulted. A five pound book is a distinct burden to read, and this volume now outrates all American competitors both in bulk and weight.

A TEXTBOOK OF HISTOLOGY. By Harvey Ernest Jordan, A. M. Ph. D. 6th ed. New York and London: D. Appleton-Century Co. Inc. 1934.

Some pedagogical losses have been incurred in the resetting. One is the placing of all subordinate descriptive matter in full size print. Discussions of blood lymphatic and nerve supply together with many lesser descriptive details, not only would appear to better advantage in fine print but also would help reduce the present cumbersome volume size. Toward the same end a still more drastic change could be made. This would consist in the total elimination of more than 100 pages devoted to a list of illustrations, a chapter on elementary histological technique and a section on detailed laboratory directions designed to fit the author's own course but of no practical value to others. Any loss to the student would be negligible.

The greatest gain in the present edition has been the introduction of some 45 additional or replacing figures. Beyond this the preface is misleading as to the amount of new material presented. The Golgi apparatus, reticulo-endothelial system and neuroglia receive new treatments. The account of gametogenesis has been condensed. Otherwise the reviewer finds almost no changes or new entries of significance.

L. B. ARRY

THE second edition of Kuntz's well known treatise² on the autonomic nervous system will find a welcome in the libraries of many a neurologist. Professor Kuntz has brought up to date the only book of its kind written in English and has thus increased its value as a reference work for those interested in the visceral side of the nervous system. He has rendered a distinct service in furnishing synopses of nearly all the important original investigations in this field and in supplying a magnificent bibliography.

All parts of the book will not share like praise by various readers. Some will feel that such sections as that on the development of the sympathetic system or that on the innervation of skeletal muscle are not unbiased by the author's own studies. Two criticisms of a general sort which are applicable to the book as a whole might be considered. It reads in monotone even to one intensely interested in the subject, a point which quickly discourages students from making as extensive use of the book as they should. One of the reasons for this fault may appear in another: the author fails to deal with subjects as critically as he might. He has not evaluated results of original investigations as carefully as should be done to give life to the book.

WILLIAM F. WENDLE.

THE second edition of Bell's *Pathology*³ contains 140 more pages than the first edition, the various topics are discussed more fully, a large amount of new material has been introduced and an entire new chapter on diseases of bones and joints has

THE AUTONOMIC NERVOUS SYSTEM. By Albert Kuntz, Ph. D. M. D. 2d ed. rev. and enl. Philadelphia: Lea & Febiger, 1934.

A TEXTBOOK OF PATHOLOGY. Edited by E. T. Bell, M. D. 2d ed. Philadelphia: Lea & Febiger, 1934.

been added. But the volume is still more than two hundred pages shorter than its nearest competitor. This is not necessarily a defect, for the book is well written with a commendable economy of words. Any contribution to the subject from the Department of Pathology of the University of Minnesota will command attention, and the present volume is no exception. It is a work of collaboration by E. T. Bell, B. J. Clawson, Hal Downey, J. S. McCartney and C. J. Watson.

Dr. Bell contributes all of the chapters on general pathology except that on "The Mycoses or Fungus Infections." This latter was written by J. S. McCartney and is praiseworthy because of its completeness since it includes several diseases omitted in most of the textbooks of pathology. The chapters on "Diseases of the Urinary System" by Bell, on

"Diseases of the Heart" by Clawson, and on "Diseases of the Blood" by Downey are essentially short monographs on these subjects and fulfill expectations based upon the reputation and experience of each of these authors in the field in which he writes. These are probably the most notable chapters in the volume and are beautifully illustrated.

Many subjects are presented with unsatisfying brevity. But few if any significant facts are omitted, although they may not be fully explained. The junior and senior medical student will be pleased to find listed in the index and at least defined in the text many rare diseases with which his clinical teachers delight to puzzle him, such as Milroy's, Landau's and Krienboeck's diseases. This fact, among many others, justifies the statement of the editor in the preface that the authors "have attempted to present the facts of pathology in such a way that the student will look upon clinical medicine as a direct continuation of his pathological studies and not as an abrupt entrance into a new field."

The surgeon will be interested, among other things, in the discussion of the value of the biopsy and how it should be performed, at the end of the chapter on tumors which was written by Bell. After a brief discussion of the prejudice of many physicians against biopsies, Bell concludes: "If we discard the biopsy it will mean removal of legs for giant cell tumors, radical breast operations for fibro-adenoma and cystic disease, removal of jaws for benign ulcers, etc. Surely the theoretical dangers of a biopsy do not offset its known value." Bell is not impressed with the alleged advantages of grading tumors as it is usually done, on the basis of "the relative number of differentiated and undifferentiated cells." He believes that "the malignancy of a tumor should be judged by its most malignant part and not by its average structure." J. P. SIMONSON

THE textbook of Cowdry¹ brings the freshest breath to the field of histology that has been experienced for some years. Here is a novel attempt

by one of America's foremost cytologists to write dynamic histology to interpret structure through function, and to present a digest of the best contemporary thought. Even the table of contents reflects the physiological approach, as witness the main section heads: (1) water, the essential vital medium; (2) the blood, the principal integrator; (3) absorptive drainage into blood; (4) chemical integration by endocrine products in blood stream; (5) intake of water, nutriment, accessory food factors and removal of waste; (6) oxygen consumption and carbon dioxide elimination; (7) regulation of constitution of blood and removal of waste; (8) rapid neural integration in response to internal and external stimuli; (9) architectural support; (10) perpetuation of the race; (11) unification, protection, and adjustment. From these headings the plan of organization can readily be grasped, and it will be immediately manifest how radically the traditional arrangement has been altered. Furthermore, there is no account of the cell as such. Its various features are discussed disconnectedly wherever they are best illustrated by the subject matter at hand. Even the tissues experience somewhat the same fate. Epithelium is first described under the thyroid gland, while the connective tissues and muscle are discussed in almost the last chapters.

From this superficial recounting of certain obvious peculiarities, it is plain that Professor Cowdry's text is indeed something out of the ordinary. When next the subject matter is scrutinized it is equally clear that no attempt has been made to present a well rounded whole. Tendons occupy eight lines and cartilage less than a page; the ureter gets no specific description, but its innervation is fully discussed; hair, sebaceous glands and sweat glands receive but one and one-half pages, whereas the pituitary gland claims nineteen, the muscles are limited to ten pages, while the blood cells alone take sixty-two.

Any criticism of these departures from the ordinary treatment is partly disarmed at the outset by the preface, from which pertinent quotations can be made to advantage:

The time is passed when a broad, even presentation of the microscopic structure of the whole body is needed. Much that is important must be omitted in order to present the most vital subjects at all adequately. Justification for this is found in comparing standard works on physiology and histology. If the latter many pages are devoted to structures which the physiologist does not deem worthy even of mention. Concentration on a few subjects affords opportunity for the presentation of some of them in their proper setting, for emphasizing the value of experimentation and of what constitutes evidence. What to omit and what to stress is the question. The usual plan is to begin with a description of typical animal cells, then to pass to the animal tissues and finally to the several organs. This is logical and time-consuming. These cells and tissues, likewise, do not come for themselves and by themselves, but function only in so far that they are integrated with the rest. Consequently an attempt is made to build up, as the discussion advances, a conception of cells and elementary tissues as the many arrangements in which they actually exist. Organs and systems are stressed in order to build the principal axes of the volume, which is to relate structure and function as the whole body—stress the real physiological side. A just criticism of most textbooks of histology is that they respectively illustrate the

¹ A TEXTBOOK OF HISTOLOGY, FUNCTIONAL SIGNIFICANCE OF CELLS AND INTERCELLULAR SUBSTANCES. By E. V. Cowdry. Philadelphia, Lea & Febiger, 1915.

obvious. Figures consuming much space merely show at a glance what the actual preparations will lead the students to discover for themselves—a much more healthy experience. They are beyond the picture-book stage. As indicated in the list of contents, the central theme of the book is the blood vascular system—the great integrator. The goal in view is that the students shall gradually visualize more and more accurately the wonderful complexity of the minute structure of the human body in terms of biochemistry, physiology, and pathology and, finally, in practice shall institute measures of assistance with due caution.

Controversial subjects have in no way been avoided, rather have they been sought out and aired. An effort has been made to present the evidence fairly and to acknowledge the labors of leading investigators.

Doubtless some of these viewpoints will not find favor with many teachers, others while sympathizing with their spirit will consider them impractical in application. The reviewer is convinced that our beginning medical students, coming as they do without any definite understanding of even the nature and properties of protoplasm or of the organization of a cell, must learn to creep before they can be expected to walk—to say nothing of running. For this reason he holds that since structure is the primary concept to be gained (before function is made to vitalize such information) a presentation which does not become wholly subservient to an ideal functional continuum is the simplest and wisest to pursue. Otherwise, confusion and discouragement to the beginner is both predictable and certain. On the other hand, with a moderate amount of previous histological experience study of this book should be a thrilling adventure. The greatest value of Professor Cowdry's text will perhaps be as a book in which collateral reading is expected. It would make, for example, an admirable companion volume to the Maximow-Bloom text which is easily the foremost in the orthodox field. With such guides the student will be enabled to get an insight into histology such as has not been possible before through the medium of the printed page.

To the medical practitioner Cowdry's *Histology* can not be too strongly recommended. It is no ordinary compilation but rather a mine of authoritative up-to-the-minute information and interpretation. If the clinician can find a page which does not offer valuable new viewpoints and unexpected rewards, then that man has been a prodigious reader and analyst of current histological literature and can well high qualify as an expert in the subject.

L. B. ARRY

FOR the preparation of his book,¹ Meaker set out to assemble completely the knowledge now well established concerning involuntary sterility, discounting the traditional fallacies and including all the modern discoveries. The purpose was accomplished admirably but this was to be expected because Meaker is one of the foremost authorities on the subject of sterility. The book is divided into three parts. In the first part the author takes up

the causes of human infertility and he discusses them under nine headings. The second part is devoted to the question of the diagnostic study of the sterile mating. Not only are the gynecologic aspects discussed but also the urologic ones. There are excellent chapters on the study of the male genitalia and semen. There are also lucid descriptions and instructive illustrations of transuterine insufflation, hysterosalpingography and postcoital examinations. Three chapters are devoted to endocrinologic investigations.

Meaker points out the value of group study of cases of sterility. In 1927 he formed a clinical group with a urologist, an internist and an endocrinologist in order to study sterility cases more thoroughly. The third part of the book deals with the treatment of sterility and in this section Meaker points out the great value of a clinical group for the intensive study of sterility cases. Before he formed the clinical group the incidence of pregnancy in his sterility cases was 2.6 per cent whereas the frequency of gestation has been 50 per cent in the series of cases studied by the group. Meaker realizes, however, that for many reasons, groups are not feasible in all cities, hence he describes the minimum treatment which a physician can carry out by himself. Urologic as well as gynecologic treatment is outlined. As regards surgery to overcome tubal occlusion, Meaker has had phenomenal success, because of the 19 patients on whom he performed salpingostomy 9 conceived. Concerning endocrine causes of sterility the author found the prognosis to be fair in the pituitary cases, excellent in cases of thyroid deficiency and poor in failure of the ovaries. Contrary to most physicians Meaker has seen good results follow the oral use of anterior pituitary preparations.

Throughout the book there is evidence of the author's comprehensive grasp of the subject of sterility not only of the physical factors involved but also of the psychic ones. Excellent advice is therefore given concerning both factors. The book deals with its subject so completely and rationally that it should be carefully studied not only by physicians who are especially interested in sterility, namely, gynecologists, urologists, and endocrinologists, but also and more particularly by general practitioners.

J. P. GREENHILL

THIS imposing volume² by Brailsford, dedicated to the memory of Sir Robert Jones, constitutes a distinctly important event in the evolution of the literature of clinical radiology. Beautifully printed on excellent paper in large type with well spaced lines its excellent diction literally tempts the reader to linger longer in the study of its rich pages. Chapters are devoted to the normal findings in the skeleton at birth and the various congenital, dystrophic and traumatic factors influencing the rate of ossification and the aberrations from the normal. After

¹ HUMAN STERILITY: CAUSATION, DIAGNOSIS AND TREATMENT. A PRACTICAL MANUAL OF CLINICAL PROCEDURE. By SAMUEL MEAKER. Meaker, M.D. Baltimore: The Williams & Wilkins Co. 1934.

² THE RADIOLOGY OF BONES AND JOINTS. By James F. Brailsford, M.D., M.R.C.S. (Eng.). Baltimore: Williams Wood & Co. 1934.

a few introductory pages of general discussion of the various pathological findings, the major portion of the book is devoted to a detailed study of the various regions of the skeleton and the lesions affecting them. The last hundred pages are devoted to a general consideration on bone changes in systemic and localized disease, and a final chapter on bone tumors. A lengthy bibliography concludes the work.

Special stress is laid upon the value of periodic radiographic examinations in studying normal and irregular growth, in observation of the progress of systemic and localized disease, and before, during, and after the exhibition of various forms of treatment. The lapse of a few weeks may supply the clinician with X-ray evidence of great value, though the preliminary X-ray findings may have been of slight or no value. Apart from setting forth concisely an account of the bone changes seen in health and disease, the author's aim has been to indicate the significance of the roentgen findings. Every effort has been made to include in this work the most recent advances already recognized in roentgen ray departments and journals but not yet adequately appreciated or accepted by general textbooks. In the opinion of the reviewer the task has been well done.

JAMES T. CASE

THE work entitled *Tuberculosis of the Lymphatic System* the author covers the subject in great detail with particular reference to the more common regions of gland involvement. His introductory chapter wherein he traces tuberculosis of the glands back to the early Greek and Egyptian conceptions of the etiology is particularly interesting to the student of medical history.

The author discusses in great detail bacteriology, pathology, chemistry and pathogenesis in this condition. The anatomy of the lymphatics is ex-

tensively described and beautifully illustrated. In the two chapters devoted to the subdivision of cervical lymph nodes, a clear picture is given of their involvement, the pathology, clinical course, diagnosis, and differential diagnosis, and the treatment, medical and surgical.

Of great practical interest is the discussion of tuberculosis of the tracheobronchial and abdominal lymph nodes. The outline of the care of the disease is a résumé of the treatment, in all its phases, and is especially to be commended for the statistical details of medical and surgical results.

This book can be recommended as an excellent text for the student and the general practitioner. The index, which is placed at the conclusion of each chapter is an elaborate and very useful compilation of all recent writings on the subject.

W. A. HARRINGTON

AN *Introduction to Gynecology*¹ is exactly what its name implies. This book was written primarily for third year medical students and is an outgrowth of a series of notes which the author has used for some time. The book is well written, each subject being presented simply clearly and briefly. It will doubtless prove to be a profitable and popular one for students.

This second edition has been made a more complete text by the addition of a short synopsis on treatment in each of the chapters dealing with diseases, although anatomy, pathology, and diagnosis are still emphasized. The bibliographies at the end of each chapter have also been expanded.

Recent advances in gynecology, such as the Friedman test for pregnancy, the Schüller test for carcinoma, and the use of the colposcope have all been included. It is unfortunate that the chapter on the endocrines has not been brought up to date in a similar manner.

ALBERT E. ROBERTS

Franklin H. Walker

FRANKLIN H MARTIN

OUT of the hardy pioneer spirit of two families, the Martins of Canada and the Carlins of Pennsylvania each coming west by caravans in the late 1840's and settling on adjacent farms in Wisconsin, grew the friendship and marriage of Edmond Martin and Josephine Carlin, to whom a son Franklin, was born in 1857.

Franklin Martin's childhood was a happy one in spite of the sacrifices of his pioneer forebears the loss of his father in the Civil War and the remarriage of his mother and the uniting of two families of children, the Martins and the Mungers. Under moral and religious influences Franklin developed into a ruddy sturdy industrious lad receiving his elementary education by the sweat of his brow.

Aunt Mary and Uncle Addison Carlin were a dominating influence for good in his life. He worked as farm hand brickmaker carpenter, janitor and later as school teacher. In 1872 he left home for Minneapolis to study. In 1874 he returned to Wisconsin and entered Elroy Seminary. And then he decided to become a doctor.

His first professional hero was Dr McLaren Miller, of Oconomowoc, and, later Dr William Spalding of Watertown in whose office he first worked as janitor, in his spare moments reading a book on anatomy which he memorized.

In 1877 he came to Chicago with just enough money for carfare and tuition, and at the suggestion of Nicholas Senn who signed his certificate of matriculation he entered the Chicago Medical College which is now the medical department of Northwestern University. It was here that he met as instructors Nathan S Davis Sr William E Quine William Byford Ralph Isham John H Hollister, and Edmund Andrews all of whom were a great influence in his medical career. He loved the fire and enthusiasm of Quine Davis and Andrews but he also loved the rockbound stability of John Hamilcar Hollister, who later became his father in law and who was a stabilizing and stimulating influence throughout his entire medical life.

His first domicile as a bachelor with young Frederick Parkhurst was at 1133 South State Street, where they cooked their own meals. During vacations of these years he returned to Wisconsin and again worked as brickmaker, school master and carpenter earning his own tuition and living expenses.

His first meeting with John B Murphy and Lewis Linn McArthur was at the time they were taking Cook County Hospital competitive examinations.

He entered Mercy Hospital where he worked with Dr Lorenzo Potter as an interne in 1880. He received his degree March 30, 1880 at the memorable old Plymouth Church at 26th Street and Michigan Avenue which was to remain his church home until its closing in 1915.

During these medical school days he was given the opportunity to earn some money by caring for the patients of some of his professors. It was during these years at Mercy Hospital that antiseptic surgery and the bacteriologic theory of medicine began to take great hold and he was intensely interested in the first local attempts at the prevention of infected wounds and in the struggle against the spread of typhoid fever which was at that time a serious menace to the health of Chicago.

In 1881 he began his medical practice, boarding with the Lord family at 2227 Wabash Avenue and meeting there his life long friends, Frank Bowles, James Chapman and Charles Nicola. He joined Plymouth Church and met Isabelle Hollister whom he courted and married May 27 1886. To her his autobiography is dedicated and with her he had a long and beautiful companionship. She it was who became the great inspiration of his remarkable career.

WILLIAM R. CURRIE

FRANKLIN H. MARTIN—THE SURGEON

FRANKLIN H. MARTIN graduated in 1880 from the Chicago Medical College which later became the Northwestern University Medical School. He served as an interne at Mercy Hospital, Chicago, during that period in the evolution of surgical technique when little was known of antiseptic surgery and practically nothing was understood of aseptic surgery. At this hospital he received his first practical experience and training in the art of surgery under the tutelage of Edmund Andrews and other masters of surgery of that day. The death rate following major operations was extremely high in this era. The progress in knowledge and his own application of what it taught soon extricated Martin from the paraphernalia of antiseptic technique and he among the first in America began to practice aseptic surgery.

One of Dr. Martin's first contributions to surgery was the founding of a Post Graduate School and Charity Hospital and this accomplishment was predicated upon his understanding of the need for disseminating the rapidly increasing knowledge of aseptic surgery. He recognized that this information must be imparted to the older men in the field who were attempting to carry out surgical procedures in the outlying communities distant from teaching centers. This early thoughtful consideration of the need for the education of the actual workers in the field and his desire to help them was the motivating factor of his later activity in developing organizations for the elevation of the standards of surgery and the continuous education of all surgeons.

During the past twenty years the honors and distinctions he has received as an organizer of the medical forces during the World War and as the instigator and the builder of the American College of Surgeons have led many to forget him as a surgeon. He was however always pre-eminently the surgeon and as such was held in high esteem by the men of the generation with whom he was associated.

In his early work as a gynecologist, before the perfection of aseptic technique made abdominal section safe, he did much to popularize the operation of tying off the uterine arteries through a vaginal incision, thus controlling the hemorrhage and inhibiting the growth of myofibromata. As a result of this operation otherwise hopeless cases were benefited and some cured.

Dr. Martin was a pioneer in experimental surgery on animals. His surgical curiosity led him to turn to an investigation of methods for perfecting a technique for the implantation of the ureters into the colon. The recorded data

of these investigations and the principles he established remain the foundation of all subsequent progress that has been made in this vexing problem. He performed one of the first operations for the removal of a diseased urinary bladder followed by the implantation of the ureters.

Surgical literature abounds with his contributions to a wide variety of subjects. These studies were made largely on conditions pertaining to surgical gynecology.

Dr Martin's surgical acumen was great, and he frequently astonished his young associates by his logical and accurate diagnoses. He was averse to exploratory incisions for information and he never knowingly performed unnecessary or questionable operations. Frequently younger co-workers, who in their enthusiasm suggested operations not clearly indicated, were admonished to be conservative.

While at first the work he did was confined to gynecology, he became one of the outstanding abdominal surgeons of the West. His technique was most meticulous, his handling of tissues gentle and dexterous, though a fearless and rapid operator, he was never over radical, and his conclusions relative to pathological conditions and their operability were based on sound surgical judgment.

In that era when abdominal tumors were not recognized or attacked at an early stage of their growth, many patients came to his Post Graduate Clinic with enormous neoplasms. If the indication for operation was clear with no serious contra-indications, he never refused to give these sufferers relief. A less courageous surgeon would have hesitated. The many excellent results in these seemingly hopeless cases attest the excellence of his judgment and the perfection of his technique. He was ever conscious of the human equation in all of his work.

He was a teacher of surgery from the beginning of his career. Any knowledge he imparted to his classes was founded upon wide reading and upon his personal and practical experience and observation. His clarity of thought and directness of expression made any subject under discussion readily understandable and his deductions were so logical and the conclusions so sound that they profoundly impressed his listeners. His commanding personality and dynamic force enhanced his ability as a teacher and these so impressed his assistants and younger associates that he passed on to them many of his attributes. As a developer of young men during their formative period in surgery, he had few equals among the teachers in this department of medicine. All of the men who were his assistants and closest associates, many of whom later achieved success in their professions, were stimulated by his inquiring mind and influenced by his kindness and generous consideration.

It was in the capacity of a teacher of surgery that he realized the necessity for a broader dissemination of the rapidly accumulating facts relative to practi-

cal surgery. This realization of the requirements of the men in the smaller communities who were doing surgery prompted the initiation and development of the Clinical Congress of Surgeons of North America.

His conception was that the surgeons who had fewer opportunities for study could learn faster and their knowledge of the basic principles of practical surgery would become greater if the chance were afforded them to watch the teachers of surgery and surgeons who had a larger surgical experience at work in their own workshops. Thousands of surgeons in the United States and Canada can bear witness to the value of his inspirational thought which originated in the mind of this Master Surgeon.

In later years came his dream of the American College of Surgeons, which he made a reality. The early vicissitudes and obstacles that were encountered in the organization of this great group of men did not daunt his untiring spirit, he recognized no barrier as insurmountable in achieving his purpose. As a result of his great vision, his courage, his indomitable will to succeed, and his unusual ability as an organizer, he has builded the American College of Surgeons which will endure in perpetuity as a monument to his understanding of the need for continuous surgical teaching in its broadest sense.

Looking back over his completed life, we are impressed with his great vision, his love for his fellow man, his appreciation of the ways to advance human welfare through education, and his untiring energy and industry. His work, as he had outlined and planned it, was finished. His memory commands our respect and admiration for the manner in which he worked to the end with the same aggressive spirit and determination which characterized his long and useful life.

We honor his memory as one of the great surgeons of his generation.

FREDERIC A. BESLEY

FRANKLIN H. MARTIN—THE FRIEND

A faithful friend is a strong defence and he that hath found such an one hath found a treasure. Nothing doth counterail a faithful friend and his excellency is unspeakable—Ecclesiastics I I 14 and 15

THE passing of Franklin Martin removes a unique personality from the medical world. His versatility and the variety of fields in which he labored with such phenomenal success will naturally furnish ample material for an interesting chapter in American Medicine. Many will speak of him as an educator, an investigator, as an organizer and leader of men, but those who enjoyed the privilege of intimacy with him will think first of him as a friend.

It was a characteristic of his early boyhood to attract and attach to him his companions, as with a band of steel, and this power lasted throughout the years of a long and useful life. That the record may be clear, it may not be out of place to recall to the generation of physicians who have known Franklin Martin that he was one of those constructive or creative dreamers whose accomplishments are to be measured far more by what the man himself meant to others than by recital of achievements. From the dreams of this man, whom I have known intimately since 1900, have sprung the greatest surgical journal of the age—*SURGERY, GYNECOLOGY AND OBSTETRICS*—the Clinical Congress of Surgeons of North America, the American College of Surgeons, and the Gorgas Memorial Institute.

How did this come about? I am powerless to suggest an answer other than may be implicit in the personality of one who was a friend and a man. When I say that he attracted friends, the wrong impression may be given, for it was not easy to win one's way into the inner sanctuary. He was by nature sensitive and shy, his approach quiet and dignified, no rush of insincere greeting to all and sundry. But as one came in contact with this eminently sane and simple man, one became aware of his abundant resources, and perhaps suddenly a shy touch of his quiet humor would sweep aside the veil of shyness and let one glimpse the lovable being within. Certain elements we all instinctively recognize as essential in the true friend, among them, first, courage and kindness and perfect candor. Courage was one of his chief attributes. He no doubt believed with Barrie, that it is the lovely virtue—a rib of Himself that God sent down to His children. To those who knew him intimately it is needless to speak of his kindness, his interest in the younger generation, and the promptness with which he recognized and encouraged merit in the younger members of the profession.

He was born on a farm and grew up among surroundings conducive to quiet thought. Much of his constructive thinking was done while walking in the great out of doors, for which his autobiography reveals his wholesome love. Nothing pleased him more than to have one or two of his friends join him in long walks during which he discussed various problems in which he was interested. More than once flashes had come during these happy jaunts that later became basic principles in one of his projects. In his autobiography he mentions the Clinical Congress of Surgeons of North America as having been conceived as he walked the deck of a ship cruising in the Mediterranean and those who have shared such jaunts with him can easily visualize his methods of thought and how his schemes of successful organization were launched. His love for out door life naturally attracted him to golf. His congenial side was at its best with his friends on the golf links, and for many years it was his chief recreation. Throughout this country and abroad there are many who remember and appreciate his charm and a lasting friendship that started on the golf course.

He had a way of attracting and binding people to him in spite of the fact that he was often very frank in discussion. Fearlessness was one of his chief attractions and even in hot argument he could maintain his point without losing his friends. There were necessarily many trying situations that arose during the development and direction of large organizations but his keen insight, resourcefulness, judgment, and sincerity were never questioned, and his policies usually prevailed. When organization was finally effected, his friends remained his friends for his candor and patient courage withstood the storm and stress of the process through which the end had been attained. After all the true estimate of an individual can be best obtained from those with whom he labors daily. His subordinates adored him, labored constantly in his behalf and respected his strict discipline, knowing full well that he observed equally with them the rules governing the organization.

No man liveth to himself alone and it would be wholly ineffectual to offer such comments as I can make upon Franklin Martin without acknowledging in full measure the help he had from the very remarkable woman, his wife, Isabelle Hollister Martin. How well they understood each other, how much he deferred to her judgment, how wise she was in counsel, and how prompt he was to abandon certain problems of which she did not approve. Very few who did not know them intimately could appreciate how much she figured in his life, how necessary she was to his happiness, and how much his success has been due to her sound judgment, loyalty, and companionship.

Franklin Martin has left a splendid heritage to the medical profession. No bequest could be more useful than the sound principles he enunciated and wove into the fabric of the institutions he evolved for the benefit of the human race. To me the greatest inheritance is *The Joy of Living*, an *Autobiography*, which

typifies the man and the friend—for it expresses his attitude toward life. If one has read this fascinating book one will find how beautifully it expresses his ideas and it shows, too, the real worth of the man and his confidence in his eventual success. From the very start of his life there is no note of appeal for sympathy, for the hardships he endured, no appeal for pity, but through the narrative, as through his daily life, running like a thread of gold woven into it, there was *real* joy of living. And because of his simplicity, goodness, honesty and sincerity, I know of no man in civil life who could, by the mere suggestion of needing or wanting them, summon more true and influential friends to his side.

The loyalty of his thousands of friends should be a pledge to foster and bring to full fruition the ideals and aims to which he devoted his life.

C. JEFF MILLER.

FRANKLIN H. MARTIN AND SURGERY, GYNECOLOGY AND OBSTETRICS

DR. MARTIN was fundamentally an idealist. A close personal and professional association for thirty five years gives me some authority to speak. Few members of our profession have been more misunderstood. This misunderstanding arose because he was possessed of an extreme sensitiveness and a reluctance to approach people or speak in public that to many will seem unbelievable. As a result of this characteristic he often seemed autocratic, though this was a pure defense reaction. His own unintentional disclosure of this trait is found in a sentence taken from his autobiography, *The Joy of Living*. In speaking of his hesitation in beginning his first laparotomy he said, "Was I a coward?" This was a bracing thought. "Have the courage to do the thing you believe to be right but that you are afraid to do." It became my slogan—a sentiment that during all my life has urged me to action a few times (I hope) with success and many times (I am sure) to my detriment.

His mind arrived with lightning speed at logical conclusions that most of us reached only after prolonged deliberation. His impatience drove him forward without the help of the support that would have come had he been content to wait until more slowly reasoning minds had caught up with him. This impatience helped to give the impression that his actions were often autocratic.

He had little or no desire to accumulate wealth. Money meant nothing to him but the means of establishing the children of his imagination. He realized however that for them to succeed and to attain permanence they must be placed upon a secure financial foundation. This is well illustrated by an account of the origin of SURGERY, GYNECOLOGY AND OBSTETRICS and of his plans for its ultimate disposition.

In December 1904 Dr. Martin invited Drs. F. A. Bealey, William R. Cubbins, John Hollister, and myself to his home at 3210 Lake Park Avenue, where he outlined his plan for the founding of the journal. His conception was of a journal divorced from any commercial association which should be founded, owned and directed by members of the profession. It was to be an example of the best art of printing; it should present in adequate form the new developments of surgical science but should always be a practical journal for practicing surgeons. It should be based on sound financial principles yet never seek to pay dividends to stockholders; it should rather use any profits to increase the service of the journal and insure its stability.

Thirteen Chicago surgeons supported these altruistic principles by subscribing for small blocks of stock. Later when Dr. and Mrs. Martin began to plan for the disposition of the journal they purchased this stock at a profit to the original stockholders.

During thirty years under Dr. Martin's direction the journal has adhered to this original conception. From the beginning Mrs. Martin has held a large part of the stock and she also has been in full accord with Dr. Martin's ideals. Because of Dr. Martin's wise planning the journal now rests upon a secure financial foundation and owns the land and buildings at the corner of Rush and Erie Streets which adjoin the College of Surgeons.

Dr. Martin's manner of administering the various organizations for which he was responsible may be illustrated by relating his conversation with me when organizing the journal. He called me to his office and said "I want you to assume charge of the scientific pages of the journal. Make the journal the best in the world scientifically and artistically. Do not be influenced by any body or anything except the quality of the contributions and the limitations of space. That's all." While he always took a leading part in any expansion or new activity, yet never in the thirty years did he let personal friendship, expediency, or advertisers betray him into seeking to influence the acceptance of any article. Nor did he interfere in any way with the administration of the department. It was the same with other associates. He expected results but gave complete freedom of action and support in any difficulty. His loyalty to his associates and friends was so great that not infrequently it surpassed what should have been expected. Except in the face of incontrovertible evidence of incompetency, he defended them both privately and before the public.

The first number of SURGERY GYNECOLOGY AND OBSTETRICS appeared on July 1, 1905, with the leading article by the chief of the Editorial Board, Dr. Nicholas Senn, upon "Iodine in Surgery with Special Reference to Its Use as an Antiseptic." The ideals of its founder and the character of the journal soon brought contributions from leading surgeons of the United States and Canada and from abroad in sufficient number to insure the journal's immediate success.

In 1908 a British edition was established under the editorial guidance of A. W. Mayo-Robson (later Sir Arthur) and other leading British surgeons. Five years later, after much thought, the INTERNATIONAL ABSTRACT OF SURGERY was added. It was determined that the ABSTRACT should be not a mere desultory collection of material but a discriminating selection from the world's literature by a board of specialists. Arrangements were made with the leading abstract journals abroad for the early exchange of their material. As a result a complete bibliography of the world's surgical literature has become a part of the ABSTRACT.

After Senn's death Dr. John B. Murphy, whose enthusiastic support had been no small factor in establishing the journal, became chief of the Editorial

Board Upon his death he was succeeded by Dr William J Mayo For many years Dr Mayo was in active charge of the Editorial Department To his vision and judgment has been due the discriminating character of the editorials Lately Dr Donald C Balfour has successfully assumed this responsibility

Although the chronicling of scientific progress has been its primary objective, the journal has sought also to foster the cultural aspects of surgery and to honor those who established and perfected its principles Under the supervision of Dr Alfred Brown, 'Old Masterpieces in Surgery' acquainted the oncoming generation with the history of surgery Under the direction of Dr William J Mayo and Dr Donald C Balfour the department of "Master Surgeons" has recorded the achievements of the surgeons of the western hemisphere and aroused our pride in their accomplishments

The journal is known and read wherever medicine is practiced It has a large number of subscribers abroad and penetrates into little known centers in Asia, Africa, and the islands of the Pacific The medical libraries of the world have its numbers filed as a permanent record of the advances in surgical knowledge during the fruitful period spanned by the publication of SURGERY GYNECOLOGY AND OBSTETRICS

It has been the desire of both Dr and Mrs Martin that after their deaths the journal with its real estate should become by gift the property of the American College of Surgeons Since the holdings of Dr Martin at the time of his death in conjunction with the personal holdings of Mrs Martin gave them complete ownership of the stock their desire may be accomplished

The regents of the College believe that this final service of Dr and Mrs Martin to the College and the profession may be made a worthy memorial to Dr Martin's vision and ideals.

ALLEN B KANAVAL

FRANKLIN H. MARTIN AND THE AMERICAN COLLEGE OF SURGEONS

FRANKLIN MARTIN died Thursday March 7 in Phoenix, Arizona, where up to a few days before his death he was occupied with the affairs of the American College of Surgeons especially with preparations for the next Clinical Congress to be held in San Francisco in October

We do well to pause to pay tribute to this great leader to whom more than to any other individual the American College of Surgeons is indebted for its foundation and its development during the twenty two years of its existence With courage, imagination wisdom unflinching loyalty to the best interests of the College and with rare executive ability Dr Franklin Martin as Director General has guided its destinies

It is fitting at this time to review briefly the history of the College—a history which will be his finest monument—for his name is indelibly inscribed upon each of its multifarious activities

At the time the American College of Surgeons was founded and earlier many surgeons, particularly the members of the American Surgical Association had felt the necessity for an organization of the active surgeons which would standardize the practice of surgery To this end at the Clinical Congress of Surgeons of North America held in New York in 1912 an organization committee was appointed Thus the American College of Surgeons is the direct outgrowth of the Clinical Congress of Surgeons a Congress which was originally fostered and promoted by Dr Franklin H. Martin who suggested the formation of this organization committee of the College

Confronting this committee were two lines of procedure (1) to follow the pattern of such an organization as the Royal College of Surgeons in England and admit members only on examination or (2) to admit to Fellowship all the members of the sixteen principal societies representing surgery and its various specialties as a nucleus for the whole and then to add to that number all those surgeons in all parts of the United States and of Canada who by their training experience and achievements were surgeons in good standing

The second of these plans was adopted by the organization committee and it at once became evident that unless the College were to grow very slowly it would be necessary to make a survey of the practicing surgeons throughout the country to determine who were qualified to become the first members of the College

Such a survey was made principally by Dr Martin who visited all the leading medical centers throughout the United States and Canada. As the result of this survey, four hundred and fifty prominent surgeons met in Washington on May 5 1913, adopted the By laws rules, and regulations suggested by the organization committee and elected the first officers of the College, and the Board of Regents and Board of Governors. The original Board of Governors was comprised of the four hundred fifty founders of the College, but the By laws provided for a permanent Board of one hundred fifty members to be divided into three groups, fifty members to be elected by the Fellows at each annual meeting of the College. The government of the College was to be centralized in a Board of Regents whose decisions would be carried out by a Director-General. The recommendations for further Fellows of the College were to be made by credentials committees representing each state of the United States and each province of the Dominion of Canada. This plan was adopted at the organization meeting. Soon after the organization of the College it was decided that the College should endow itself by asking each Fellow to subscribe five hundred dollars to be paid in a lump sum or by payments of not less than twenty five dollars a year.

By this rapid start in membership and in financial support the College had a forceful momentum and was able at once to launch forth on its campaign to carry out its original purposes which are stated in the following summary of a clause of the Articles of Incorporation published in each *Year Book*. "The object for which it is formed is to establish and maintain an association of surgeons, not for pecuniary profit but for the benefit of humanity by advancing the science of surgery and the ethical and competent practice of its art.

It is my opinion that when the College was organized there was no one man who could have equaled the performance of Franklin Martin as Director General for more than to any other one man. The credit belongs to him for the foundation of the College its organization for the rapid mobilization of surgeons to form its constantly increasing membership the shaping of its policies, the solving of the many difficult executive problems which have repeatedly presented themselves. In addition to his many official trips throughout the United States and Canada, Dr Martin has promoted the interests of the College in South America and in Australia by personal visits.

Throughout these twenty two years, I have had the opportunity of observing the constructive genius of Franklin Martin at close range. I should say that except for his peculiar talents the College would not be in its present position. Franklin Martin undertook every bit of the leadership that was delegated to him and often initiated new projects. The whole picture has constantly been one of rapid construction and of militant progress, as exemplified by the many activities of the College and by the work of its Department of Hospital Standardization the Registry of Bone Sarcoma, the Committee on the Treatment of Malignant

Diseases the Committee on Fractures the Board on Industrial Medicine and Traumatic Surgery the Department of Clinical Research the organization of Cancer Clinics the Regional Meetings the annual Clinical Congress the Library which is ready to serve each Fellow by literary research and the Board on Medical Motion Picture Films

In addition to a very high level of efficiency we have our property in Chicago which aggregates in value more than two million dollars—assets which include the endowment fund land buildings and equipment

The very characteristics which have made these achievements possible inevitably sometimes seem too aggressive but in a formative period they are necessary even though they may arouse some antagonism. A lively imagination courage spirit of adventure outstanding executive ability great loyalty to a cause can never be outweighed by lesser qualities. Such characteristics speak for themselves in outstanding achievements

Dr Martin not only was intensely loyal himself but was able to inspire loyalty in those associated with him as is demonstrated by the fact that the Editorial Board and the business personnel of SURGERY GYNECOLOGY AND OBSTETRICS have remained practically unchanged since Dr Martin founded this journal with the exception of those called by death and the outstanding characteristic of the working staff of the American College of Surgeons has been its long time loyalty to its Director General Those who knew Franklin Martin best, trusted him most

All through his life and despite every disguise Franklin Martin has been shy fearless imaginative, idealistic and a dreamer Long will he be known among the great dreamers in medicine He dreamed a dream and the greatest surgical journal in the world was born he dreamed again and the Clinical Congress of Surgeons of North America appeared he dreamed yet again and the American College of Surgeons came into being

GEORGE CRILE

FRANKLIN H MARTIN AND THE GREAT WAR

FRANKLIN H MARTIN was, for half a century one of America's distinguished surgeons, more than that, he demonstrated to an unusual degree the rare gifts of administrative genius and vision. It was logical then that when the clouds of war began to hover over our land with characteristic foresight, as Secretary-General of the American College of Surgeons he should tender the services of that organization to the Surgeon General of the United States Army to aid in re-organizing and enlarging the Medical Reserve Corps. With the acceptance of this timely offer two thousand Fellows of the College, of military age immediately enrolled in the Medical Reserve and until the Armistice was signed this great organization of surgeons took the lead in every wartime medical program.

On August 29 1916 through the enactment of the National Defense Act President Wilson was authorized by Congress to appoint an Advisory Commission consisting of seven persons especially qualified in their respective fields to co-operate with the Council of National Defense in its task of mobilizing the resources of a nation dedicated to peace into a fighting force sufficiently powerful to stay a foe trained for centuries in the arts of war. Through the persistent endeavors of the Committee of American Physicians for Medical Preparedness representing the American Medical Association the Congress of American Physicians and Surgeons, the American College of Surgeons, the Clinical Congress of Surgeons of North America, and the American Surgical Association totaling a membership of ninety thousand medical men the President was convinced that the medical profession should be accorded a place on the Advisory Commission. The question then arose who, among the members of the scientific medical profession was qualified to fill this important and exacting post?

Franklin Martin was the unanimous choice of the committee and in October 1916 he was notified of his appointment by President Wilson.

The Council of National Defense consisting of six members of the Cabinet Secretary of War Newton D. Baker, Secretary of the Navy Josephus Daniels, Secretary of the Interior Franklin K. Lane, Secretary of Agriculture David F. Houston, Secretary of Commerce William C. Redfield, and Secretary of Labor William B. Wilson held its first meeting in Washington on December 6 1916 with the seven members of the Advisory Commission, Daniel Willard, president of the Baltimore and Ohio Railroad, Hollis Godfrey, president of Drexel Institute, Howard E. Coffin of Detroit, Bernard Baruch of New York, Julius Rosen

wald of Chicago Samuel Gompers, president of the American Federation of Labor and Dr Franklin H Martin

Commenting on the sentiments of the commissioners on this occasion Dr Martin said

We, as members of the Commission, had arrived in Washington with somewhat vague conceptions of our duties. We met the six members of the Council, who were equally vague as to our responsibilities, but we rapidly became acquainted. Each gave his idea of the requirements of the situation and of the immensity of the task that we must assume—and then we realized that our group in joint action, would virtually become a War Cabinet, which should not only advise but plan, execute and direct the activities of our Government in its preparation for defense in the greatest war of history. No commissioners ever entered Washington at the call of a President with more humility and with less concrete knowledge of what they were expected to accomplish.

However Franklin Martin shouldered the responsibilities of the post assigned him with characteristic eagerness, and immediately proceeded to formulate a program that would be operable when and if we were drawn into the world conflict. His department in the Council of National Defense was one of the first to establish a routine that functioned with clock like precision until April 1, 1919. The outstanding men and women in medicine and the allied specialties in association with him gave the utmost of their talents and abilities to uphold the well known devotion to service of the medical profession. Under his direction the medical resources of the nation were so adequately mobilized that a steady flow of men and materials perfectly synchronized as to supply and demand, was at all times available.

The General Medical Board of the Council of National Defense, of which Dr Martin was chairman, included the leaders in medicine, dentistry and nursing from civil life. This Board with the Surgeons General of the Army, Navy and Public Health Service and the chairman of the American Red Cross, guided the policies of the special committees composing the Medical Section of the Council of National Defense. These committees, more than a score in number, included the medical, dental and nursing professions, and covered every angle of medical preparedness. In addition to the Washington organization state and county committees co-operating with other defense agencies extended their activities into every town and hamlet in the land.

As a result of this co-ordinated effort, the General Medical Board and its subsidiary committees, more than any other one agency may be credited with the splendid showing of the medical profession in its voluntary enrollment for service. In November of 1917 there were 440 medical officers in the Army and 329 in the Navy. At the armistice there were 30,591 medical officers in the Army and 2,570 in the Navy. And in the Volunteer Medical Service Corps, an organization of physicians barred from active duty because of age, physical disability or

home responsibilities 72 219 enrolled Likewise in the nursing and dental services, enrollments far exceeded the quota set for an army of five million men

It is impossible in the limited space available here to enumerate be it ever so briefly measures initiated by Dr Martin and the programs in which he participated during the war years He worked assiduously to secure proper military rank for the doctors and nurses in the military services He toiled unceasingly to supply the government with medical men and materials to meet the demands of war His own and foreign nations decorated him—and rightly so—for conspicuous service

During the nearly two years of continuous association with Major General William Crawford Gorgas Surgeon General of the United States Army Dr Martin came to know and admire this modest physician and ultimately a warm and enduring friendship developed between the two After Gorgas death in July 1920 it was only natural that Dr Martin should be one of a group who felt that this man was worthy of a memorial—not of stone or bronze—but a living vital organization which would embody the hope of freeing the world from disease—the object to which the life of Gorgas had been consecrated As Surgeon General of the Army Gorgas instituted the policy of strict physical examination for all recruits with regular check ups at intervals thereafter This resulted in an army of physically fit men to meet the rigors of war and it is a well known fact that our soldiers maintained the highest health rate of all combatants General Gorgas often said to Dr Martin Wouldn't it be wonderful if some day a system of strict physical examination could be applied to our civil population? The story of Gorgas sanitary work in Havana and Panama is familiar not only to the scientific world but to the laity as well So in planning the memorial to perpetuate his name it was fitting that the two great works of Gorgas—personal health and sanitation—should be chosen as the basis on which the Gorgas Memorial should proceed After the institution of an ambitious nation wide program in health education it was characteristic of Dr Martin's foresight that he should vision in the Gorgas Memorial Institute an opportunity for the creation of an international research center in which the countries of Latin America where Gorgas had achieved his magnificent work in sanitation, should have a part Out of this vision has grown the Gorgas Memorial Laboratory in Panama already a recognized research center, underwritten by the United States Government and destined to play an increasingly prominent part in the fight of science against disease

Franklin Martin was above all a good soldier He was brave, he was fearless, he would not recognize defeat and once he had determined on a course his generalship untiring energy, and fighting force could be depended upon to see him through to a successful conclusion

CARY T GRAYSON

FRANKLIN H. MARTIN—THE MAN

TO paint a word picture adequate of Franklin Martin, a man who as he matured became the greatest organizer which the past fifty years of medicine has produced a man honored by his profession decorated by his own and foreign governments, is indeed a difficult task. However as it was my privilege for many years to enjoy his close friendship to me the task becomes a labor of love.

There are many qualities common to those among men who leave their names conspicuously high on the rolls of achievement of the era in which they have lived. Oft included in these are the circumstance of lowly birth and early struggles against privations combined with integrity of mind indomitable will and other steadfast qualities. There are however deeper influences which must predetermine a man's ultimate worth and nature having endowed Franklin Martin with the rugged qualities of strong character gave him also a fineness of sensibility which tempered his thoughts with keen discernment and his judgment with unfailing fairness and justice.

We see him in his youth with the spirit of D Artagnan recognizing no obstacles as insurmountable and ready for life's adventure with a happy heart. We see him passing through life retaining this happy heart and always sharing it with others. We see him at eventide with the spirit of youth and merriment still retained and then understand why it was he who wrote *The Joy of Living* for life to him had been a joy. It was not alone the joy of achievement which for him produced satisfaction for no one labor was ever finished before his restless brain had conceived or he had had another thrust upon him. It was that joy which comes from doing for others which was the motivating force behind him. And the extent of his work for others is the true measure of Martin's greatness.

In each of the great activities in which he played such a major rôle it was his clear vision which insured their lasting success. Martin had the unusual combination of not alone being an organizer but having the added quality of being able to make his organizations functionate peculiarly well after he had built them. As he was progressive in his thought, so were his organizations. Not only did they fulfill the objectives for which they were designed but became active influences for advancement with changing progressive thought. This again was evidence of his farsighted vision.

The spirit of his soldier father who sacrificed his life in public service during the Civil War influenced Martin throughout his life. He was ever ready to aid

civic organizations and took part in many projects to advance the welfare of Chicago. He was intensely loyal to his alma mater, Northwestern University of which he was a trustee for a decade, and he was an active member of the various organizations which served its alumni. He gave to the U S Army Industrial College, the Fuel Conservation Institute, and the Board of Education of Chicago much time and thought. He was international in his outlook, and participated with enthusiasm in the deliberations of the Committee on Co-operation in Latin America, the Chicago Council on Foreign Relations, the American Academy of Political and Social Sciences and the Italy America Society.

Martin had an extraordinary ability to appreciate immediately which were the most important details of any problem and to recognize instantly the right thing to do under adverse conditions. There are many instances which I might relate which are indicative of this. One, however, stands out rather vividly in my memory. On a certain night shortly after the First Liberty Loan Drive had been started, he and I were at a Broadway theater. Between the acts a drive was staged and the men who were soliciting subscriptions were meeting with poor success. At that time Martin was interested in stimulating enlistments in the Medical Reserve Corps of the United States and the lukewarm reception which the audience were giving to the request for subscriptions disturbed him. He became restless and told me he must help the men on the stage stir up some enthusiasm for the Loan. He was dressed in his Colonel's uniform and as he arose from his seat to offer his subscription, standing alone in that audience with his soldiery carriage, his chiselled face and flashing eye he made an instantaneous effect on the audience, a sight never to be forgotten. He offered his subscription for the bonds and as the audience went wild with applause not to be outdone by the soldier, they made the drive in that theater that night one long talked of. As he reseated himself beside me, he leaned over and whispered, "God knows how I'll ever pay for them" but he had saved the situation.

Martin will go down through the pages of American history as a courtly man ever actuated by the strongest principles of high Americanism. He had the simple faith of his forefathers with a strong pioneer spirit. Whenever he fought for his beliefs he was a foeman worthy of his adversary's steel. He was a rare combination of stern forcefulness and sympathetic kindness, and I believe no more fitting description of Martin as a man could be made than by a summing up in two words. Franklin H. Martin—Surgeon and Gentleman.

Sunshine was he in the winter day
And in the midsummer coolness and shade

J BENTLEY SQUIER.

BIOGRAPHICAL OUTLINE

Born in Ixonia, Wisconsin, July 13 1857 son of Edmond and Josephine (Carlin) Martin
Died in Phoenix, Arizona, March 7 1935
Educated in public schools and academies of Wisconsin
Northwestern University Medical School, M.D. 1880
Interne Mercy Hospital, Chicago 1880-1881
Member of Staff South Side Dispensary 1883-1888
Married Isabelle Hollister (daughter of John Hollister a founder of Northwestern University Medical School) May 27 1886
Professor of Gynecology Polyclinic of Chicago 1886 1888
Organized, with Dr W. F. Coleman the Post-Graduate Medical School and Hospital of Chicago 1888
Gynecologist, Woman's Hospital, Chicago for many years from 1887
Organized the Charity Hospital, Chicago 1889
Organized SURGERY GYNECOLOGY AND OBSTETRICS 1905 the INTERNATIONAL ABSTRACT OF SURGERY 1913 Editor-in-Chief 1905-1935
Organized the Clinical Congress of Surgeons of North America (now the Clinical Congress of the American College of Surgeons) 1910
An organizer of the American College of Surgeons, 1913 Fellow Regent and Director General, 1913 1935 President 1929
Trustee Northwestern University Chicago 1921-1931 Medical Counsellor 1929-1935
Member Advisory Commission of the Council of National Defense 1916-1921
Chairman, General Medical Board Council of National Defense 1917-1918
Colonel, Medical Corps, U. S. Army during period of Great War 1917-1919 with A. E. F. for three months
Founder and Chairman Board of Directors Gorgas Memorial Institute of Tropical and Preventive Medicine 1921-1935
Honorary Adviser United States Army Industrial College 1925-1935

MEMBER OF MEDICAL AND OTHER ORGANIZATIONS

American Medical Association Chairman, Section of Gynecology and Abdominal Surgery 1895
American Gynecological Society President 1919 Member of Council, 1910-1922
Southern Surgical Association
Congress of American Physicians and Surgeons
Chicago Gynecological Society President, 1894
Association of Military Surgeons
American Medical Editors and Authors Association Member Board of Governors
American Society for the Control of Cancer
American Hospital Association
Northwestern University Alumni Association President, 1931 Director Division on Medicine, 1921-1935
Northwestern University Associates
American Legion Hyde Park Post
Chicago Literary Club
American Association for the Advancement of Science

DECORATIONS HONORARY DEGREES AND MEMBERSHIPS

LL.D. Queens University Belfast 1925 University of Wales, Cardiff 1928 University of Pittsburgh, 1933
D.P.H. Detroit College of Medicine and Surgery 1926

D Sc. Northwestern University Evanston 1927
 Companion of the Order of St. Michael and St. George (C M G) 1919 in recognition of services rendered to the British Empire during the Great War
 Distinguished Service Medal U S 1926 in recognition of services rendered during the Great War
 Commander of the Order of the Crown of Italy 1931 in recognition of aid in founding Loyola Base Hospital, which served the fourth and sixth armies on the Italian front
 Honorary Fellow Sociedad Peruano de Cirugia
 Honorary Fellow Academia Nacional de Medicina de Rio de Janeiro, Brazil
 Corresponding Member Sociedade de Medicina e Cirurgia de Sao Paulo Brazil
 Corresponding Member Sociedad de Cirugia, Buenos Aires, Argentina
 Corresponding Member Academia Nacional de Medicina Buenos Aires, Argentina
 Honorary Member Sociedad de Obstetricia y Gynecologia Buenos Aires Argentina
 Honorary Member Eta Chapter Alpha Kappa Kappa Fraternity

SEQUENCES OF EXPERIMENTAL BACTERIAL INFARCTION OF THE FEMUR IN RABBITS

GENE H. KISTLER, M.D. ¹ UNIVERSITY ALABAMA

INFARCTS were produced in the femurs of rabbits by particulate suspensions of charcoal and the sequences in such lesions were correlated with a discussion of some of the more obscure clinical conditions which essentially are focal necrosis of bone marrow tissues (17). The experiments reported demonstrate that infarcts occur in bone in spite of its great vascularity and abundant blood supply and that the metaphyses are more vulnerable than other regions. Since the embolic substance charcoal is extraneous and was injected in relatively large amounts experiments simulating more nearly the conditions occurring spontaneously in bone were undertaken with dead and living bacteria as emboli. By these procedures it seemed possible to produce septic and aseptic necroses of bones where a circulation disturbance (infarction) is the common factor and thus offer an explanation why these lesions occur so frequently in certain locations.

For many years it has been known and generally accepted that osteomyelitis not directly the result of injury, tuberculosis and various forms of so called aseptic necrosis and osteochondritis occur almost exclusively in the epiphyses of bones and the metaphyses of growing bones. The essentials in the production of these lesions and a satisfactory explanation of their occurrence in special regions more often in certain bones have aroused considerable interest. Experimental investiga-

tion and speculation. The evidence available favors that a nutritional disturbance is an important factor in some and infection in others but there is no accepted concept of the details involved.

Lexer and his associates stated that the smaller branches of the nutrient artery of the shaft do not pierce the epiphyseal plates and that the resulting hyperemia and sluggishness of the blood stream favor the deposition and retention of bacteria in the metaphyses. According to Axhausen, Koenig and many others occlusion of one of these terminal vessels may produce infarction of the tissues. This is the most prevalent theory of how hematogenous foci of osteomyelitis occur. Wilensky stated that thrombosis following embolic occlusion of vessels is an important factor. Phemister (29, 30) believed that such an embolus must be infected to produce noteworthy necrosis. According to Wakeley the blood vessels at the actual margin of the metaphysis are in a series of narrow and inelastic tortuous loops an arrangement which favors embolic infarction. Schulze noted that the metaphyseal capillaries have an elongated hairpin shape while the subchondral epiphyseal capillaries form a coarse network with nodular projections toward the cartilage. He assumed that in the elongated capillaries the blood current is slow and that there are no protective cells of the marrow since India ink injected into young dogs was

absorbed more slowly from the metaphyses than from the diaphysis tissues.

According to Kolodny, Eliason and Ferguson and Harbin and Zollinger one or two small vessels pass from the diaphysis to the epiphysis through the conjugal cartilage but have little significance. Harbin and Zollinger stated that the line may also be penetrated by vessels in rickets and in some other pathologic conditions. Harris (13) demonstrated by cleared preparations previously injected with carmine glycerine that diaphyseal vessels do not pierce the cartilage plates to enter the epiphyses. Vogt (1878) and Jahn (1892) demonstrated that mechanical disturbance or removal of epiphyseal cartilage plates interferes with growth of the long bones. More recently Meisenbach, Haas, Bohlman and others found that various chemical and solid materials placed within the metaphysis decrease the longitudinal growth of bone and that transplants of epiphyseal cartilage do not produce bone. They emphasized the need of a metaphyseal blood supply for osteogenesis. According to the clinical observations of Sever, separation of the epiphysis usually takes place between the metaphysis and the epiphyseal cartilage plate and as a result of the anatomical arrangement

there may be no gross interference with the circulation or viability of the epiphyseal cartilage columns. Occasionally authors have hypothesized the presence of physiological end arteries in the growth centers.

Since osteomyelitis is so much more common in children particularly boys, and often in the extremities, external trauma always has been considered a factor in localizing such a focus. Likewise trauma to the articular surface and subchondral bone tissues of epiphyses is thought by many to be responsible for the various forms of osteochondritis. Such injuries as these are not similar to the trauma of weight bearing during which *coxa vara* deformity at the hip is produced or an epiphysis is slipped resulting from some underlying alteration in the structure of the bone or cartilage. According to Reischauer and his statistics, trauma probably is of no importance in the origin or localization of osteomyelitis or tuberculosis of bone. He considered that these diseases attack the metaphyses because of active cell proliferation and tissue metabolism in certain metaphyses more frequently than others because of a greater rate of growth.

In an extensive review of necrosis in different bones, Harbin and Zollinger correlated these diseases often referred to by various specific names into one group known as osteochondritis of the growth centers. They believed that the etiology of these is unknown but that direct trauma or indirect as a result of increased stress and strain from the body forces seem important while heredity may be a factor. Wardle stated that slipping of the head of the femur may be due to localized osteomalacia which tending to occur in the areas of most recently formed bone weakens the attachments of the epiphyseal cartilage. In his discussion of tuberculosis of bone, Oberzimmer emphasized the resemblance of these cuneiform regions of necrosis in articular extremities to infarcts. These foci are subchondral and usually triangular the base toward the articular surface. He concluded that the genesis of these necrotic regions is not understood and if they are true infarcts, emboli in some of the vessels or an obliterating endarteritis should be found.

Fig. 1. Marked acute aseptic necrosis of the head and neck and medial bending of the proximal end of femur 45 days after infarction by agglutinated killed staphylococci. X7

In his discussions of silent foci of osteomyelitis and chronic fibrous osteomyelitis, Phemister (31-32) stated that these lesions often are metastatic, remain symptomless for a long time, and usually occur near the ends of bones. He said that the etiology of these lesions is not known neither do we know the relation of chronic fibrous osteomyelitis to bone cysts, osteitis fibrosa cystica, giant cell tumors and pyogenic osteomyelitis. According to his views, embolism and infarction may play a rôle in the production of some of the lesions, but pyogenic bacteria of low virulence must also be present because some of the cases of chronic fibrous osteomyelitis reported could not be explained on an aseptic necrosis basis alone. Compère cultured a green-producing streptococcus from a lesion in the astragalus that histologically was similar to osteitis fibrosa. Greenwood, Pease, Phemister, Brunschwig and Day (33) and many others have isolated various organisms from patients with Koehler's, Kienboeck's, Osgood-Schlatter's, and other related diseases which often are placed in a group as aseptic necroses or osteochondritis of individual bones. According to Hallermann, arteriosclerotic changes of the nutrient blood vessels of the upper end of the femur are often associated with osteoporosis of that portion of the bone. It seems that practically all diseases of bone, except those attributed to dietary or glandular disturbances, have characteristics in common

which probably are associated with peculiar structural arrangements of the subchondral tissues that make them more vulnerable than other bone tissues to disturbances in blood supply. The individual differences among these diseases therefore may be based upon the presence or absence of infection, and if infection is present, upon the mass and virulence of that particular organism.

Experimental studies have aided little in understanding fully the infection and necrosis of bone tissues. Senn refers in his text to experiments by Struck, Krause, Mueller and Rodet who injected animals intravenously with pyogenic organisms, usually staphylococci isolated from osteomyelitis, and noted acute suppurative lesions in bones, joints and many other tissues. They often found the foci in bones of young animals near the epiphyses without accompanying fracture or other external evidence of injury. Mueller also produced in young animals a few characteristic foci by injecting tuberculous material. Recently Schulze observed similar results which support the view of Lexer concerning the mechanism of localization of foci in bones. Jackson noted wedge-shaped regions of necrosis in the metaphyses of bones during an attempt to produce arthritis in rabbits by the intravenous injections of streptococci. From his studies of experimental osteomye-

litis in dogs, none of which lived longer than 48 hours. Starr concluded that infection starts in the metaphyses, extends along the epiphyseal line to the cortex and periosteum, and probably spreads along the shaft through the Haversian canals. Kuwahata produced abscesses in bones of young but not of adult guinea pigs by injecting a strain of *Staphylococcus aureus* into the heart. The incidence of the abscesses was much greater when the diet of these animals was deficient in vitamin C. He suggested that a peculiar vascular arrangement in the metaphyses and less resistance of the tissues than elsewhere may play a part in localization of the foci. Halde

man and others studied the acute osteomyelitis in animals produced by injecting a culture of a pyogenic organism through an opening in the cortex. Such experiments do not repeat the conditions with spontaneous lesions and do not aid in understanding why pyogenic infections occur in certain regions of bone. It seems there are no controlled observations of lesions produced in bones where living and dead bacteria have been used as emboli, thus determining any relation between bland or septic infarction to focal necroses of bones. Also, the exact location and tissue structures

of early lesions have not been studied in detail either clinically or experimentally in animals.

EXPERIMENTS

A hemolytic strain of *Staphylococcus aureus* cultured from the blood stream of a man with a subperiosteal abscess and fatal septicemia was injected through the principal nutrient arteries of the femur of rabbits by the method used for infarction of this bone by a particulate suspension of charcoal (17). To agglutinate the organisms and partially or completely sterilize the suspensions from 0.1 to 0.4 cubic centimeter of one tenth normal sulphuric acid were added 2 to 48 hours before injection. The suspensions were obtained by washing 24 hour agar slant cultures with 1 cubic centimeter of normal salt solution. The degree of agglutination usually marked was demonstrated by gross and microscopic examinations and cultures of the suspensions were made at the time of injection. It was thought that mildly septic infarcts compatible with life could be produced by decreasing the number and virulence of organisms acting as emboli.

Rabbits between 3 and 8 weeks of age were chosen in order to study the localization in active growth centers of bland and septic emboli. The agglutinated cocci were forced into the chief nutrient artery of the shaft by

Fig. 9. Multiple subchondral abscesses of the great trochanter and marked necrosis in the metaphysis of the femur in Figure 8. There is beginning liquefaction within the epiphyseal cartilage plate. $\times 9$.

retrograde injection through the femoral artery with other outlets temporarily ligated. In a similar way, the suspension was directed through the deep femoral artery, one branch of which enters the trochanteric notch of the femur, another encircles the capsule of the hip joint and a third becomes the principal source for the vessels in the ligamentum teres. Because of the small caliber of the latter vessels exact and well controlled isolated infarction of the head of the femur was not possible. Material introduced into the principal nutrient artery of the shaft was directed almost entirely to the medullary canal of the diaphysis. A small amount occasionally was distributed to the periosteum.

Each rabbit received from 0.2 to 0.6 cubic centimeter of the agglutinated living or killed suspension and died or was killed from 12 hours to 48 days after operation. A few were injected with non-agglutinated living staphylococci but all died within 2 days. The animals that received killed organisms be

Fig. 10. Acute metaphyseal subchondral necrosis and partial separation of the ossifying portion of the head epiphyseal plate in a femur 14 hours after injection of a partially agglutinated suspension of living cocci. $\times 16$

haved like normal animals except occasionally one favored the injected leg in hopping and held it partially flexed at the knee and hip. Several of the animals injected with living organisms died within 24 hours after operation. Others lived as long as 17 days depending upon the mass injected and the viability of the cocci as determined by culture at the time of operation. The local disability of the leg produced by septic emboli was proportionate to the severity of the osteomyelitis and it varied from slight decreased weight bearing

Fig. 12. Multiple foci of septic necrosis in the distal metaphysis of a femur 2 days after injection of a suspension of partially agglutinated living staphylococci. One focus is situated within the epiphyseal cartilage plate. $\times 75$

to marked rigid flexion at the hip and knee. A pure growth of staphylococcus similar to the strain injected was obtained from joints with exudate that were contiguous with the femurs injected.

The femurs were fixed in Klotz solution No. 1 containing formalin to 10 per cent, decalcified with 4 per cent nitric acid and cut into proximal, middle and distal segments. These blocks were then doubly embedded in celloidin and paraffin from which sections were cut and stained with hematoxylin and eosin.

As a further control on anemic infarction in the femur in young rabbits and for comparison with embolism produced by this strain of agglutinated staphylococcus, one group of animals received a suspension of charcoal in 5 per cent gum acacia according to the above procedure.

RESULTS OF EXPERIMENTS

Agglutinated suspensions of killed Staphylococcus aureus. Gross examination of injected femurs demonstrated infarction and subsequent changes similar in general to those observed after occlusion of the medullary blood vessels by charcoal and significant of interference with growth of the bone ability to bear weight and of osteogenic reaction within the periosteum. The disturbance in overall length growth of the bone amounted to as much as 2.5 millimeters in 8 days and

Fig. 13. Complete necrosis of the head and its epiphyseal line and focal necrosis of the neck of a femur 8 days after septic infarction by agglutinated living staphylococci. The short neck is depressed and forms a right angle with the shaft. $\times 5$

this shortening was greatest at the end of the bone receiving the largest amount of the material injected. Femurs infarcted for 3 weeks or more tended to regain this decrease in length. Necrosis in the neck of the femur often produced shortening and medial bending of this portion and allowed the head to droop (coxa vara) and rotate forward. When the head epiphysis was infarcted along with the proximal metaphysis of the shaft it seemed to flatten slightly and overhang the neck at its shelving edge. Occasionally the external surface of the cortex most prominent near one end of the shaft was roughened by new bone and the soft parts were removed with some difficulty. Necrosis was not observed in the knee or hip joint capsules or in the other soft tissues of the thigh after injection of killed agglutinated organisms.

Histological preparations of femurs that received killed agglutinated organisms through the nutrient artery to the shaft demonstrated infarcts and anemic necrosis confined almost entirely to the metaphyses and endosteum. The smaller and more recent infarcts were wedge shaped and were situated in the tissues immediately beneath the columns of epiphyseal cartilage without noteworthy changes in the medullary tissues of the diaphysis or of

Fig. 14. Septic necrosis of the inner and tissue reaction within the outer lamellae of the cortex in the femur of Figure 13. There is also partial necrosis in the adjacent marrow tissues. $\times 16$

the adjacent bony epiphysis. About one-fifth of the epiphyseal cartilage plate along the edge in apposition with the base of the infarct of the metaphysis also was necrotic and a definite line of demarcation was present between it and the remaining living portion. Occasionally there was partial separation within the epiphyseal plate along this line. Large infarcts occupied the entire metaphysis and in these the necrosis was most marked about the columns of ossifying cartilage toward the center of the growth region. The infarcts were poorly stained fragmented medullary tissues and devitalized bone and cartilage with considerable peripheral hemorrhage. When the changes occurred in the cortical bone opposite the metaphysis there usually were similar regions along the endosteum of the shaft elsewhere but still without noteworthy alteration in the medullary tissues of the central portion of the shaft.

Infarcts present for 6 days or longer demonstrated a separation and reorganization process present on all sides of the wedge except at the base beneath the epiphyseal cartilage plate. This consisted of many small blood vessels in a loose poorly cellular and edematous fibrillar stroma that invaded the debris of the necrotic region. It later became more dense fibrous with a few clear spaces and a variable number of osteoclastic giant cells. Compact and spongy new bone was formed when the infarct extended to the cortex and often new osseous tissue was laid down outside the cortex in the form of an involucrum.

Fig. 15. Multiple subchondral abscesses in the distal metaphysis and epiphysis of a femur 7 days after septic infarction. (x45 to eight colonies grew on agar plates inoculated with the suspension at the time of injection.) Foci in this bony epiphysis were unusual. X16

The metaphyseal surface of the cartilage plate remained necrotic until organization of the infarct but the columns above continued to grow without being ossified so that frequently the growth line was as much as three times its normal width. Overgrowth of the cartilage did not occur at the periphery of the epiphyseal plates because of periosteal and capsular collateral circulation. This was especially true at the posterior edge of the distal plate where many muscle tendons insert and at the lip of the head epiphysis where the capsule of the hip joint is attached to the neck of the femur. As organizing tissues replaced the infarcted region and where the blood supply was adequate the long columns of epiphyseal cartilage cells narrowed to about their former length and osteoid tissue and new bone were formed in irregularly arranged interlacing spicules. The level of the metaphyseal surface of the plate at the time of

Fig. 16. Marked deformity, scarring and new bone formation in the proximal end of the femur of Figure 15. There is a distinct line at the level of arrested growth. X75

infarction was frequently marked by transverse spicules, some of which extended entirely across the marrow cavity. Vessels occasionally pierced the central portion of the growth line from the epiphyseal body and aided in restoring function to the growth center. When the injection of emboli was made such that a bony epiphysis was infarcted with its corresponding metaphysis, there was complete necrosis of the conjugal epiphyseal cartilage and a tendency for it to be narrower than usual and collapsed. This was most marked in the epiphyseal cartilage line of the head of the femur where the force of weight bearing caused the head to droop and to overhang the neck. Impaired nutrition and growth produced shortage of the neck and its angle with the shaft was more acute than normal.

The primary site of embolic infarction of the femoral epiphyses was beneath the articular or other cartilage and was similar to metaphyseal infarcts beneath epiphyseal lines of the diaphysis. Such infarcts of the head of the femur were usually accompanied by regions of necrosis in the corresponding acetabula and haversian fat tissues at the base of the ligamentum teres.

Necrosis in the femurs produced by carbon emboli was more marked and extensive in the medullary tissues of the shaft than after the injection of clumps of dead cocci. There were

less definite deposits of the material beneath the columns of ossifying epiphyseal cartilage and more occlusion of larger vessels due to the greater size of the carbon particles. Revascularization and organization of the charcoal infarcted tissues required a longer time and the ultimate fibrous tissue replacement was more dense. The killed organisms produced more profound changes in the growth centers and seemed to elicit greater necrotic bone destruction by giant cells (osteoclasts) than the charcoal emboli.

Agglutinated suspensions of living Staphylococcus aureus. The gross alteration in size and contour of femurs infarcted with living were similar to but more marked than in those that received injections of killed organisms. In addition several joints contiguous to infarcted metaphyses contained exudate from which a pure culture of the organism was obtained. Some of these joints at the distal end of the femur were associated with liquefaction necrosis of the metaphysis and pathological fracture through the epiphyseal cartilage plate. There were no abscesses of the soft tissues.

Microscopic examination demonstrated anemic necrosis according to the pattern described for bland infarction combined with exudative inflammation. The latter agent intensified the hemorrhages and necrosis and elicited a marked infiltration of polynuclear leucocytes about the septic infarct. This acute pyogenic osteomyelitis very definitely and constantly began in the so called growth regions with a few small foci in the inner layers of the cortex. In preparations of recent infarcts there were masses of cocci wedged to the apices of the lacunar spaces between strands of calcified cartilage matrix. These collections were present also beneath articular and other cartilage of infarcted epiphyses and occasionally within the haversian canals of the cortex, but not in the medullary tissues of the shaft. The intimate association of the site of beginning abscess formation with the very tips of the spaces between ossifying strands of calcified cartilage matrix was striking. Partial or complete separation regularly occurred within the epiphyseal cartilage plate at the base of the metaphyseal

infarcts. The line of separation in histological preparations was straight and uniform. Its position corresponded to the limits of cartilage necrosis and to the line demarcating the extent of necrosis in epiphyseal plates at the base of infarcts produced by bland bacterial emboli. That portion (about 80 per cent of the width of the plate) remaining attached to the bony epiphysis usually maintained its viability except when the epiphysis was infarcted with the metaphysis. There often was a narrow localized zone of tissue reaction on the epiphyseal side of the cartilage plate after septic infarction of the growth center but this was slight compared to the reaction on the metaphyseal side of the conjugal cartilage.

When the metaphyseal abscesses were sufficiently large to extend to the cortex there was exudate in the canaliculi of the bone and occasionally beneath the periosteum. Necrosis of the subperiosteal tissues elicited a marked cellular and fibrous tissue reaction of the periosteum, dead bone absorption and new bone formation. Complete separation of the epiphysis occurred when the walling-off process here at the periphery of the cartilage plate was unable to maintain viable tissues between epiphysis and diaphysis. The amount of new bone formation (involucrum) about the infarcted portion of the shaft depended upon the amount of damage to the cortex and it varied from none to a wide layer. Occasionally the periosteum also was necrotic, in which event no involucrum formed and consequently the metaphyseal portion of the shaft collapsed.

The walling-off and reorganization process in septic infarcts seemed to proceed more slowly than those produced by bland staphylococcus emboli. Septic necrosis produced more new cortical and spongy bone, greater injury to the epiphyseal plates, and more disarrangement of the medullary tissues of the metaphyses than did the aseptic infarcts. In a few bones there were circumscribed regions of necrosis like encapsulated abscesses and with the return of growth activity in the corresponding cartilage line, these were pushed farther away from the epiphyses. The new bone formed outside infarcts of the endosteal

tissues was always well delimited from the dead cortical bone by cellular fibrous tissues containing osteoclastic giant cells, but sequestration was not observed.

EVALUATION OF EXPERIMENTS

The intra arterial injection of acid killed and agglutinated staphylococci through nutrient vessels of the femur in growing rabbits has demonstrated that infarcts and subsequent changes of bone can be produced by bland bacterial emboli. These infarcts resemble those produced by a particulate suspension of charcoal and probably no chemical factor from disintegrating bacteria is added to the embolic disturbance of circulation. The clumps of cocci were considerably smaller than the individual carbon particles and fewer particulate bacterial masses were injected. For this reason and because the bacteria were more readily removed from the tissues than the carbon the infarcts were smaller they stimulated less tissue reaction and healed more rapidly. Where the emboli contained living bacteria certain changes were noted which relate to septic and aseptic diseases of bone.

The wedge shaped regions of necrosis were intimately associated with so called growth centers because of the peculiar vascular arrangement and blood supply of subchondral tissues. The localization of the infarcts and collections of living staphylococci between the strands of calcified epiphyseal cartilage demonstrate that this is the site of lodgement of embolic material. Killed organisms were not demonstrated directly beneath the ossifying cartilage because the bacteria were small in number and rapidly disintegrated in the tissues. Carbon particles did not reach these tissues as a rule because they were too large for the caliber of the vessels. The terminal capillaries in the finger-like tissue spaces of the metaphyses, which erode the epiphyseal cartilage matrix in the process of growth probably are not loops but rather are thin walled tubes which elongate as the erosion of cartilage progresses. The absence of abscesses in the soft tissues, even when living agglutinated bacteria were injected into the deep femoral artery supports this belief. Appar-

ently the clumps were sufficiently small to pass through the usual capillary bed. Necrosis beneath ossifying cartilage and epiphyseal separation even when the cocci were not agglutinated also favor a distinctive capillary pattern in the growth centers. This capillary arrangement is present beneath all cartilage of the epiphyses but the number of actively proliferating vessels is probably dependent upon the amount of bone formation. Since growth in length occurs in the metaphyses, these tissues are more vulnerable than the subchondral tissues of the epiphyses where growth is by expansion. Following embolic occlusion of the capillaries there was retrograde thrombosis the extent of which depended upon the size and number of particles injected and the collateral circulation. The tissue changes with infection added to this vascular disturbance by mycotic emboli depended upon the virulence and mass of living organisms. Therefore it is possible clinically to have all stages between anemic infarcts and acute abscesses from bacterial emboli either pyogenic or specific as tuberculosis.

The tissues in the center of the metaphyses were more vulnerable than those beneath the periphery of the epiphyseal cartilage plates because the latter have a periosteal blood supply. This was demonstrated by regular occurrence of small infarcts beneath the center of the epiphyseal cartilage and by ingrowth of blood vessels and reaction tissues from the peripheral portions of the metaphysis and from the periosteum. Further necrosis of the metaphyseal ends of the epiphyseal cartilage columns and interference with ossification were not so marked near the cortex particularly in regions opposite the insertion of muscles and tendons. Infarcts at the distal end of the femur tended to be slightly above the center of the plate since the articular cartilage extends far up the bone anteriorly and the periosteum has no muscle attachments. Complete separation in the epiphyseal line occurred only when the region of necrosis included the cortical and periosteal tissues of the metaphysis.

Assuming that periosteal collateral circulation to metaphyses is a constant or uniform

potential source of nutrition the vulnerability of a given growth center is proportionate to its size. For this reason metaphyseal infarcts septic or aseptic more often occur in large bones, such as the femur tibia and humerus and in these subjacent to the broad epiphyseal cartilage plates. Also other things being equal infarcts occur most commonly where there is greatest growth activity since it is here that compact strands of calcified matrix and the lacunar spaces between them are longest and have many developing capillaries that project into the eroded cartilage. Subchondral foci of infection and bland infarcts may occur in the epiphyses after the epiphyseal lines are completely ossified so long as there is enchondral ossification in the secondary centers. The predominance of lesions in some over other small bones probably concerns individual differences in structure and blood supply. External trauma may localize an infection but only in so far as it disturbs the vascular pattern of a portion of bone or accentuates the dearth of collateral circulation in regions that are normally more susceptible to infection and nutritional disturbances.

The uniform occurrence of necrosis at the base of the infarcts in the metaphyseal ends of the columns of epiphyseal cartilage demonstrates that these tissues which are about to be converted into spongy bone and osteoid tissue have a diaphyseal blood supply and that there is no noteworthy vascular communication between the epiphyses and diaphysis. The amount of the necrosis in the cartilage plate was constant and marked the level where complete separation within the line occurred when the necrosis extended laterally to include the cortex and periosteum. Since the columns of cartilage continued to grow from above even after complete separation within the line cartilage proliferation is dependent upon epiphyseal blood supply and should be distinguished from ossification. Necrosis of the plate occurred only when its bony epiphysis was infarcted. A collateral circulation to the metaphyses from the epiphyses through the conjugal cartilage was formed in some of the infarcted metaphyses. Occasionally after marked infarction of the metaphysis the distal end of the femur had a club-shaped

deformity due to the relative expansile overgrowth of the knee epiphysis.

Bland infarcts and abscesses localized also beneath the endosteum and within cortical bone. This suggests that the capillary arrangement among spicules of spongy bone and within Haversian system to some degree may be similar to the vascular pattern described for enchondral ossifying tissues. However the extent of involvement of the cortex opposite an infarct of the metaphysis was not constant as if limited, and it seemed to be dependent upon the size of the infarct. Septic infarcts extended along the epiphyseal cartilage plate and included considerably more compact bone than those produced by a similar injection of killed organisms. The bacteria from septic foci of necrosis penetrated the subperiosteal tissues and produced suppurative arthritis. The retrograde extension of osteomyelitis from the metaphysis to the more central portions of the shaft was considerably less than its spread laterally due to the abundant blood supply of the central medullary tissues. Some of the abscesses of longer duration were farther from the epiphyseal lines because of reorganization and return of function to the growth centers. Involucrum formation seemed to be stimulated by the presence of necrotic compact bone and was present only where the necrosis had not included the periosteum. This was similar to new bone formation by the periosteum observed after infarction of the femur with charcoal emboli (18). The removal of dead bone by osteoclastic giant cells seemed considerably more active in infarcts produced by staphylococci living or dead than in those caused by charcoal emboli.

Deformity results when a portion of a bone is unable to withstand the stresses placed upon it. The alteration in contour depends upon the amount of injury to normal structure present within the bone and to the forces which tend to produce distortion. The type and virulence of bacteria when present in foci of necrosis are important in determining the amount and acuteness of the disease and subsequent deformity. Bacterial infarction of the proximal end of the femur produced various degrees of collapse and hypoplasia of the

neck (coxa vara) and the neck rotated anteriorly so that the entire femur was displaced inward slightly. Infarcts in the head of the femur caused this epiphysis to flatten and overhang the neck at its shelving edge. Femurs infarcted for 3 weeks or more partially regained the growth deficiency either by hyperplasia in an unaffected growth center or organization and resumption of function of the infarcted metaphysis.

Transverse spicules of bone often were observed in infarcted metaphyses after organization and return of function to the growth centers. These marked the level of the ends of epiphyseal cartilage columns at the time of infarction and they correspond to the so-called lines of arrested growth described by many authors (6, 14, 25) in various acute illnesses and metabolic disturbances.

SUMMARY

Masses of bacteria living or dead may act as emboli in producing septic or aseptic infarcts in bone. The subsequent changes are modified by infection when the infarcts are produced by infected emboli.

These infarcts occur regularly beneath ossifying cartilage especially in the metaphyses due to relative poor collateral circulation in subchondral tissues and to the presence of open end-capillaries immediately beneath ossifying columns of cartilage. The occurrence of foci in some metaphyses more than in others probably is dependent upon the diameter of the epiphyseal cartilage plate and the rate of bone growth within the metaphysis.

The extent of bone destruction and subsequent distortion depends upon size of the infarct and if infected further upon the mass and virulence of the bacteria. Exudative arthritis may follow the spread of a metaphyseal focus of infection along the epiphyseal line to the periosteum.

Metaphyseal growth centers and the adjacent portion of epiphyseal cartilages obtain their blood supply from the periosteum and nutrient vessels of the shaft. The epiphyseal portion of the cartilage plates, about four fifths of the thickness depends upon the circulation of the epiphysis. Separation of

epiphysis and diaphysis occurs along a plane between the limits of the two sources of nutrition within the conjugal cartilage plate.

The stimulus of necrotic cortical bone and adequate periosteal blood supply are necessary for the formation of new compact bone (involucrum).

Lines of arrested growth may be present in metaphyseal infarcts produced by clumps of living or dead staphylococcus aureus.

SYMPHETECTOMY AS A PRELIMINARY TO THE OBLITERATION OF POPLITFAI ANEURISMS

WITH A SUGGESTION AS TO SYMPHETIC BLOCK IN CASES OF LIGATURE, SUTURE, OR
THROMBOSIS OF LARGE ARTERIES¹

CLARENCE E. BIRD, M.D., F.A.C.S., LOUISVILLE, KENTUCKY

THE incidence of extensive gangrene requiring amputation following operations for the relief of popliteal aneurisms is estimated by the writer to rest between 8 and 15 per cent. This approximation takes into consideration a probable number of unsuccessful cases which are not reported in the literature and for this reason the figure is higher than that obtained by Professor Matas (6) who found among 154 personal and reported cases of popliteal aneurism operated upon by his three methods of aneurismorrhaphy up to 1915 8 cases of gangrene or 5.2 per cent.

Doctor Matas' personal success has been extraordinary and the papers indicate that in his own cases he has had practically no gangrene. This splendid achievement has been obtained first by the use of his compressor (4) and tests for determining the adequacy of the collateral circulation (5) second by a correct clinical judgment as to the type of aneurismorrhaphy indicated, and finally by strict adherence to the principles of his operations (3).

Nevertheless, if others share my feeling they approach the obliteration of a popliteal aneurism with misgivings and will be grateful for any and which may provide further assurance that the collateral circulation will be adequate. Twice in cases of my own I have observed the development of a false aneurism during the preparatory 2 or 3 weeks of repeated compression of the femoral artery above the sac by Matas method. In neither instance was any direct pressure exerted upon the sac itself and I do not believe that the false aneurisms arose because of instrumental damage to the walls of the true sacs. The presence of an enlarging false aneurism causes compression of the motor and sensory nerve fibers, increases the discomfort of the patient, hurries the operator to carry out his procedure before the time he would otherwise elect, and

increases the likelihood of infection in the field either before or after the operation, or both. An advantage would be gained if an obliteration could be done safely at any time after admission to the hospital even almost immediately if indicated.

In the first case of which I speak the collateral circulation as tested by the method of Matas was doubtfully satisfactory. The dorsalis pedis and posterior tibial arteries were palpable but were weaker on the side of the aneurism. A sympathetomy was considered but was not carried out. Immediately after the obliteration of the sac the appearance of the toes and foot was discouraging and the outcome in brief was a mid thigh amputation necessitated by gangrene.

In order to avoid a possible repetition of this unfavorable result it was determined in the second patient to take advantage of the work of Mulvihill and Harvey who showed by well controlled experiments on dogs the tremendous advantage to be gained in the immediate postoperative period if a sympathetomy is done at the time of the ligation of the external iliac artery. When the sympathetomy was not carried out the subcutaneous temperature of the corresponding foot dropped gradually over a period of 2 to 7 hours to or almost to room temperature remained there for from 2 to 6 hours then gradually rose to body temperature on an average of 13 hours after the ligation of the external iliac artery. On the other hand when the sympathetomy had been performed the drop in temperature did not occur. Sympathetomy prevented, therefore, an 8 to 14 hour period of partial ischaemia. It is assumed that these experiments on dogs may be applied directly to the popliteal artery of man and there appears to be no reason to doubt the correctness of this view. Such ischaemia if applied to an already diseased

¹From the Department of Surgery of the University of Louisville School of Medicine and the Surgical Service of the Louisville City Hospital.

human leg could hardly fail to be damaging or disastrous. Sympathectomy, on the other hand, should provide a wide margin of safety.

A short summary of the pertinent findings in the record of the second patient follows:

W. R. (L. C. H. No. 35926), a single colored dishwasher aged 20 years, was admitted on June 1, 1934. He first noted a swelling in the right popliteal space 2 months before. This rapidly enlarged causing him to limp because of inability to extend the knee joint completely. Pain, extending down the leg, began 2 weeks before admission. He had had a penile sore several years previously but had not been treated by incisions or injections. There was no history of trauma to the popliteal space. The patient had been troubled all his life by frequent slight nausea and copious, effortless regurgitation of food. These symptoms had not been relieved by the removal of his appendix 10 years previously.

Examination showed normal development and slight undernourishment. The pupils and eye grounds were normal. There was no periorbital edema. The nasal septum. The teeth were carious, the gums infected. Fluoroscopic examination and barium studies revealed a thoracic stomach which extended from the upper aperture of the thorax to the level of the diaphragm, where, after some delay the barium emptied directly into the small bowel. The balance of the intestinal tract appeared normal. The heart was slightly enlarged and an electrocardiogram showed borderline right axis deviation and sinus arrhythmia. The radial pulses were equal, strong, regular without sclerosis, rate 88. Blood pressure registered 120/80. There was an old lower right rectus operative scar. The knee jerks were present and approximately equal on the two sides.

In the right popliteal space was a large, tense, expansile pulsating tumor over which in certain positions of the limb a delicate thrill could be felt. A loud bruit with systolic accentuation was heard over the entire tumor. The skin and deep fascia were tense over the mass, the borders of which could not be made out. The knee, leg and foot were moderately swollen and the veins below the level of the tumor were engorged. Elevation only partly emptied them. There was moderate pitting edema of the extremity on the side of the aneurism. The feet and legs were moist and equally warm to touch. Flexion and extension of the knee were limited by painful tension in the region of the mass and by pain shooting down the leg. The dorsalis pedis and posterior tibial arteries were unusually easy to palpate on the left but on the right no pulsations could be felt. The dorsalis pedis artery on the right stood out as a pulseless cord. The femoral artery by pressure did not change the heart rate. Obliteration of this vessel stopped the expansile pulsation thrill and bruit in the popliteal

mass and on elevation of the leg during compression the mass became soft and plastic. The appearance of the knee suggested fluid in the joint but the patella did not float. There were no gross sensory changes in either leg but there was weakness of the anterior tibial and peroneal groups of muscles on the right. Injection of neoskiodan into the femoral artery produced an imperfect visualization of an almost spherical mass 6 centimeters in diameter in the midpopliteal region. No collaterals were seen.

The Matas test, carried out with a mechanical constrictor and an Eschmarch bandage showed no turn of blood to the subungual capillaries in from 2 to 5 minutes after removal of the bandage. Observation of the descending flush, however, was difficult to make in the presence of the black skin and cult to make in the presence of the black skin and further we were unable to be absolutely sure that some blood was not occasionally leaking past the constrictor. The veins did not fill well from below and my impression was, on the whole, that we were dealing with an unsatisfactory collateral circulation.

The blood Wassermann reaction was four plus. The blood hemoglobin (T) 80 per cent, red blood cells, 4,050,000, differential count and cent white blood cells, 7,750. The urine showed one plus albumin and an occasional pus cell. Analysis of the fluid obtained from the thoracic stomach by a nasal tube with its tip 32 centimeters from the nostril showed a specific gravity of 1.032, free hydrochloric acid 28 and total acid 46.

The temperature varied from subnormal to 100 degrees F. with a pulse of 80 to 100. Compression of the femoral artery just above the adductor hiatus was carried out for 5 to 10 minutes every 2 hours each day. Shortly the patient began to complain of increased pain in the knee and leg and the tumor and all of the tissues of the knee and leg enlarged. The knee was held flexed to 100 degrees for comfort.

On June 9, 1934, a right lumbar sympathectomy was performed under spinal anesthesia, severing the ram and removing the ganglia and trunk between the levels of the second lumbar and the first sacral vertebrae. A warm dry leg resulted which in contrast to the left, was hyperemic and exhibited a diffuse dusky red blush throughout. The slight fever persisted and the pain became more constant as the popliteal swelling increased in tenseness. The Matas test was now more difficult to carry out on account of the pain and because of the necessity of flexion but there was no longer any doubt as to the adequacy of the collateral circulation. After removal of the Eschmarch bandage there was always a return of color to the sole of the foot and to the tissues beneath the nails within one minute and a half. No pulsation returned to the dorsalis pedis and posterior tibial arteries. The weakness of the anterior tibial and peroneal muscles became a total paralysis with marked hypaesthesia of the deep and superficial peroneal areas.

On July 5, 1934, an obliterative endoaneurismorrhaphy was carried out under spinal anesthesia. A

curved longitudinal incision, convex medially was made over the popliteal space. The semitendinosus muscle was found thinned out and displaced. No nerve trunks, large veins, or lymph nodes were exposed. The deep fascia was incised over about 8 centimeters of the aneurismal surface, which was discolored with blood pigment and somewhat edematous. The circulation was temporarily occluded by a blood pressure cuff which had been placed around the upper thigh. The sac when opened longitudinally was found to be 3 millimeters thick, and contained fresh and old blood clots as large as one and one half adult fists. The posterior surfaces of the femur and tibia were palpated but there was no break through to the bone or joint space. The endothelium was intact about the upper and lower orifices and along the external side of the sac, but elsewhere the lining was shaggy and false and extended upward and downward irregularly between the muscular layers. Closure of the upper and lower orifices was accomplished with fine interrupted silk sutures. On removal of the pressure from the femoral artery above, there was only slight oozing. One geniculate vessel was closed from the inside and the large sac was obliterated with three layers of interrupted silk sutures. The deep and superficial fascia was closed with interrupted silk without drainage. A loose bandage and posterior plaster splint were applied and the patient was returned to bed with the leg slightly below the level of the heart and with a warm cradle over the extremities.

From the first there was no doubt as to the adequacy of the circulation. Color returned to the nails almost immediately after release of compression and the return was as rapid or slightly more rapid than on the opposite side. Forty-eight hours after operation there could be felt and seen a pulsating artery beneath the skin on the anteromedial surface of the knee. The dorsalis pedis and posterior tibial vessels on the right remained pulseless. The slight fever and the peroneal paralysis persisted and the deep tissues beneath the cleanly healed external wound gradually became more swollen. On the nineteenth day after operation a soft, deep, indolent abscess was opened, and about 200 cubic centimeters of odorless, *Staphylococcus aureus* pus was evacuated. Thereupon the temperature returned to a consistent normal for the first time since admission and the wound healed rapidly. The motor paralysis was still present on discharge on July 31, 1934.

Had it not been that due to the enlarging false aneurism and the pain the sac must be obliterated promptly I should have been tempted to await the arrival of the Pavax apparatus (2) which Doctors Mont Reid and Louis Hermann have so kindly sent us from Cincinnati for use in the vascular clinic and I would feel more enthusiasm in reporting the evident benefit of preliminary sympathetec-

tomy in this case, were it not for the fact that the procedure will without doubt shortly be superseded by the use of their effective stimulant of collateral circulation. By its use the diameter of the collateral arteries can not only be increased before operation but the entire limb may be placed in the boot under negative pressure immediately after operation, in this way counteracting the tendency toward sympathetic overaction in a limb recently traumatized. In fact the limb will be subjected to the negative pressure before the passive dilatation due to the spinal anesthetic, if such be used, has worn off so that the precious collaterals may never be subjected to the action of the sympathetic fibers until the period of jeopardy is passed. It is true of course that during the period before this apparatus becomes generally available the procedure of sympathetectomy or sympathetic block, may be of use in the cases under consideration and also in the management of other aneurisms and tumors which involve large arteries of the extremities (1).¹

A further suggestion may be made. It is probable that a temporary block of the appropriate portions of the sympathetic chain with alcohol will continue to be valuable in those cases in which because of the presence of fracture apparatus or dressings, the Pavax apparatus cannot be utilized. I have in mind especially serious fractures or injuries because of which it is found necessary to suture or tie the large arteries or those cases in which there is present arterial thrombosis which plays a devastating part.

SUMMARY

Lumbar ganglionectomy was performed as a preliminary to the obliteration of a popliteal aneurism thereby avoiding the constrictor action of the sympathetic fibers on the collateral arteries during the dangerous early postoperative period.

In the same way advantage should be derived from sympathetec ganglionectomy or sympathetic block carried out before or immediately after operations or injuries which

The preliminary sympathetecomy reported in another of the sympathetic block previously found to have been reported by Gage in the operative management of cases of syphilitic aneurism of the common iliac artery.

involve obstruction or threatened obstruction to large arteries of the extremities

The rationale for these procedures is contained in the work of Mulvihill and Harvey.

In suitable cases the pavaex apparatus of Herrmann and Reid should accomplish the same result without interference with the sympathetic fibers themselves

OBSTRUCTIVE LESIONS OF THE UTERUS AND THEIR COMPLICATIONS¹

ARTHUR H. CURTIS, M.D. F.A.C.S. CHICAGO, ILLINOIS

A REALIZATION that cervical strictures are of clinical importance was impressed upon me very gradually in incidental to interest in the pathology of chronic leucorrhoea. A survey of my records reveals frequent notations of cervical strictures as early as 1920. Yet I did not awaken to an appreciation of their true significance until some years later.

In 1929 at the inaugural meeting of the Baltimore Obstetrical and Gynecological Society I discussed the incidence and clinical importance of cervical obstructions.² To the best of my knowledge these lesions, other than complete stenosis, and hydrometra and pyometra incident to cancer and to radium therapy, had previously been recognized only as pathological curiosities, and there is apparently still a tendency to overlook their rôle in the etiology of pelvic disturbances.

It is scarcely necessary to emphasize that the impassable cervical canal of many children means a distinct physiological

The frequency of obstructions of the cervix should again be emphasized they are very common indeed. But my chief aim at this time is a presentation of important pathological changes which are encountered in the more serious cases, in the hope of arousing greater interest in this subject.

CASE 1. V. B. aged 51 years, with a history of a normal menopause at 48 years, suddenly developed a profuse purulent leucorrhoea 1 month prior to entrance into the hospital. Aside from having given birth to three healthy children after normal labors, the previous obstetrical and gynecological history was negative. There had been no instrumentation or infection to account for the sudden appearance of the purulent discharge.

Attempted dilation under anaesthesia revealed a canal so firmly strictured that the obstruction could not be overcome, and a vaginal hysterectomy was resorted to. The uterus, opened by anterior incision after removal, had a constricted granular canal with multiple firm osseous bands and pocketed chambers containing purulent material above the various sites of obstruction.

This case with multiple strictures and pocketings of the uterus of unknown etiology complicated by infection of the retained secretion eventuating in postmenopausal profuse purulent leucorrhoea, exemplifies the pathology which is often responsible for senile vaginitis. With cessation of the menstrual function and shrinkage of the cervical lumen lesser lesions of varied etiology which cause no annoyance in earlier years suffice to make complete obstruction. There is first a retention of mucoid secretion then contamination of the retained material and finally a pyometra, or more commonly a seepage through of the purulent accumulation when pressure sufficient to overcome the obstruction has developed within the uterine cavity. A spontaneous cure may result but dilation or more extensive surgery is usually required.

CASE 2. E. B. aged 67 years, married 43 years, entered Passavant Memorial Hospital July 23, 1934. She had one child, at the age of 35 years, after a diffi-

Fig. 1. Case 2. Non-malignant, tumorous obstruction of endocervix with dilation and pocketing above on right. The uterine musculature was soft and senile, and friable almost to the point of rupture in the pocketed region. (Two-thirds actual size.)

¹ Presented before the New York Obstetrical Society, January 8, 1935, and before the Society of Gynecology of New Jersey, January 6, 1935. From the Department of Obstetrics and Gynecology, Northwestern University Medical School and Passavant Memorial Hospital, Chicago.

Fig. 2 Case 2. Low power photomicrograph of endocervical tumefaction, consisting of a stroma honeycombed with a multitude of glands and cystic gland spaces. $\times 9\frac{1}{2}$

cult spontaneous labor with normal recovery. Menstruation, always normal, had ceased suddenly at the age of 50.

The patient complained of a watery leucorrhoeal discharge of many years' duration sufficient to require a pad. Occasional slight dark bloody spotting had been present for 3 years; a profuse gush of thin dark fluid occurred 3 days before entrance. Examination revealed a large cystocele and a slight amount of dark brown discharge from the uterus, which was of generous size and descended nearly to the vulvar orifice. The cervix was considerably lacerated; the perineum relaxed.

Operation. Dilation, accomplished without difficulty despite an obstruction in the upper cervix, was accompanied by passage of several cubic centimeters of mucoid and watery brown retained secretion. Curettage was abandoned because the uterine wall was found to be soft and thin, and perforation appeared imminent. The prolapsed uterus was then removed vaginally, normal tubes and ovaries were palpated, the cystocele was corrected and the perineum repaired.

When the soft senile uterus, which was 4 inches in length, was opened, a tumefaction high in the endocervix was bisected. A similar nodulation, in size and appearance resembling the surface of a large preserved strawberry, was present on the posterior wall and terminated above at the level of the internal os of the greatly elongated cervix. The body of the

uterus had a capacious cavity, especially in the lower uterine segment, which was pocketed on the right; the uterine wall was soft and senile, thin, and friable almost to the point of rupture in the pocketed region above the tumorous obstruction. Remaining traces of accumulated dark fluid were still present here. In the wall of the fundus were a few small fibroids, one protruding into the cavity (Fig. 1).

Microscopic examination revealed the tumefaction of the endocervix to be a non-malignant growth, consisting of a stroma honeycombed with a multitude of glands and cystic gland spaces of varied size up to many millimeters in diameter. Active pro-

Fig. 4. Case 3. The external os was stomatous, the cervical canal for 2 centimeter above was narrowed and rigid, passing over suddenly into a sacculated endocervix, the wall of which was roughened and furrowed. (Two thirds actual size)

hyperplasia of the glands is apparent but there is no evidence of malignancy (Figs. 2, 3).

In this case there had developed without discoverable cause non-malignant tumorous nodulations in the endocervix characterized by glandular hyperplasia and multicystic degeneration with the production of partial obstruction of the uterus.

CASE 3. E. J. aged 44 years, married 21 years, entered Passavant Memorial Hospital July 23, 1934. There had been an appendectomy, a removal of both fallopian tubes and one ovary, and a resection of the other ovary, also a diagnostic curettage, in 1919 in St. Paul. The following year having moved to Chicago the patient was given local treatments for relief of persistent leucorrhoea. These treatments, administered at various times during 1920 included endocervical applications of tincture of iodine and of silver nitrate of varied strength. It is recorded also that the patient suffered from pelvic discomfort, and a semi-fluctuant mass was palpated in the region of the right broad ligament.

Ten years later in 1930 when I first saw this patient there was persistent pelvic pain, evidently from adhesions, and a fist sized soft mass was still present in the deep right pelvis. At the next visit in 1934, immediately before entrance into the hospital, marked pelvic distress was still present. The patient gave history of regular menstruation every 28 days of 4 days duration until the preceding year since which time the periods had become slightly irregular but continued to be normal in amount and

painless. Two months prior to entrance, immediately following a menstrual period, there had been a sudden gush of yellow fetid discharge. This was profuse for 1 or 2 days, followed by moderate irritating, dark watery discharge which persisted until entrance into the hospital.

Operation. The appendix, tubes, and ovaries were found to be absent except for a tarry mass in the right broad ligament in which were some remnants of ovarian tissue. Massive pelvic adhesions almost completely concealed a heavily dragging uterus, to the right of which was the broad ligament haemorrhagic accumulation just referred to. A complete abdominal hysterectomy was performed and the associated lesions were attended to.

The removed uterus was of generous size 3½ inches in length, the peritoneal surface studded with fibrous tags, the tubes absent. At the time of opening the uterus the external os was found to be stomatous, the cervical canal for 3½ centimeter above was narrow, granular and rigid, passing over suddenly into a sacculated space containing prune juice material. The endocervix in the sacculated region was rough and furrowed (Fig. 4).

Microscopic study of the pocketed rough endocervical wall above the structured region reveals extensive glandular hyperplasia, the columnar epithelium of the glands having undergone extensive metaplasia into squamous epithelium. In some regions the squamous epithelium is seen replacing the columnar cells. In other regions the process is complete and the squamous layer has attained massive thickness. There is a marked tendency to proliferation but no evidence of invasion (Figs. 5, 6).

In this case the stricture of the lower cervix is evidently ascribable in part to infection in part to instrumentation and local medication. Above the strictured incompletely obstructed lower cervix the epithelium of the pocketed and dilated endocervix subjected to the irritation of accumulated menstrual fluid and debris, has undergone marked leucoplasic metaplasia into squamous epithelium.

CASE 4. M. C. aged 27 years, unmarried, entered Passavant Memorial Hospital October 22, 1934. She had been seen 5 years previously when a tentative diagnosis was made of chronic appendicitis and early endometriosis. The uterus at that time was sharply anteverted. The patient then wandered elsewhere and the appendix was removed through a McBurney incision; the pelvis was not explored.

Upon her return to me the patient stated that for the past year there had been continuous pelvic discomfort. Menstruation was fairly regular of a gushing character, excruciatingly painful, occurred at intervals of 23 to 25 days and was of 7 days duration, muddy during the final days. There had been persistent dark brown menstrual flow for an entire month prior to entrance. For many months there

Fig 5 Case 3 Photomicrograph of endocervical wall above structure (see Fig 4) revealing leucoplasic metaplasia of columnar epithelium into squamous epithelium (The cavity in the illustration is a fold not the cervical canal) $\times 50$

Fig 6 Case 3 High power photomicrograph revealing squamous cell metaplasia of endocervix of uterus shown in Figure 4 $\times 90$

had also been a watery mucoid leucorrhoea associated with cramps, beginning a few days after menstruation and continuing for 3 or 4 days.

Examination revealed the uterus somewhat fixed and huddled in retrocession the fundus curled anteriorly as in congenital anteversion. Nodulations in the cul-de-sac and in the regions of the adnexa were pathognomonic of endometriosis.

At operation a textbook picture of extensive pelvic endometriosis was encountered. It was noted that the fundus of the retrocessed fixed uterus pointed anteriorly and certainly had never been retroflexed. Tarry cysts were present in both enlarged ovaries blueberry and raspberry nodules and endometriotic adhesions completed the picture (Fig 7).

The opened uterus had a rigid stomatous canal in the lowermost centimeter with a bell shaped endocervical pocket immediately above. The endometrium of the body of the uterus was succulent and numerous small polyps were present.

In this patient with extensive pelvic endometriosis and an upright uterus a cervical stricture had apparently produced dilation above and retrograde spilling of menstrual debris and was the probable cause of the endometriosis.

Microscopic study of the pocketed endocervix at a level of a centimeter and more above the external os reveals a surface covered with festoons of hyperplastic glands. In many areas the columnar epithelium of the glands is being replaced or has been replaced com-

pletely by squamous epithelium. The squamous layer often attains a considerable thickness but there is no evidence of invasion or other changes characteristic of malignancy (Figs 8 9 10).

The pocketed endocervix of this patient was undoubtedly bathed in retained secretion just as in Case 3. And again we find extensive squamous cell metaplasia. From these cases it would appear that the pocketed mucosa above cervical strictures is peculiarly predisposed to metaplasia and in this we find two features of special interest: (1) a possible source of the cells which give rise to squamous cell endocervical cancer and (2) an irritating retained secretion which may be a stimulant to cancerous growth. It should be emphasized that we have noted repeatedly the peculiarly irritating qualities of retained fluid which escapes into the vagina and bathes the vulva.

CASE 5 W. K. aged 38 years married 4 years, nulliparous, entered Passavant Memorial Hospital July 30 1934. Increasing pelvic discomfort and severe dysmenorrhea were the chief complaints. Menstruation was fairly regular but prolonged and characterized by premenstrual spotting for a week, followed by the passage of clots with establishment of the flow.

At operation the ovaries were found to be converted into tarry cysts the left containing approximately a liter of dark bloody fluid, the right one-fifth as much. The upright body of the uterus was of double normal size and contained multiple small fibroids.

Fig. 7. Case 4. Pelvic endometriosis in a patient with an upright uterus, a cervical stricture, dilation above the stricture, squamous cell metaplasia of the endocervical columnar epithelium, and uterine polyp. Retained secretion above the stricture was probably a factor in producing the metaplasia; retrograde spillage of menstrual debris through the fallopian tubes may have caused the endometriosis. (Two-thirds actual size.)

The uterus was opened after removal and a granular endometrium was encountered. It was puckered but not definitely obstructed at the external os, and at the internal os was a rounded tumefaction similar to those found in Case 2, more than a centimeter in length with associated puckering of the indurated mucosa and distinct narrowing of the lumen.

It is to be noted in this case as in Case 4 that pelvic endometriosis developed despite the upright position of the uterus. And in conformity with my previous experience in patients with endometriosis and a well placed uterus interference with uterine drainage was again encountered, the obstruction in this case being a cystic tumorous thickening at the internal os.

Microscopic study of the tumorous area reveals fibrotic tissue honeycombed with innumerable glands and cystic glands (Fig. 11).

It would appear that tumorous obstructions of the cervix (see also Case 2) may be composed of hyperplastic glands and stroma. This tissue is not bathed in retained secretions and seemingly there is no tendency to metaplasia of its columnar epithelium.

CASE 6. R. S. aged 42 years, entered Passavant Memorial Hospital December 5, 1930. At the age of 29 years, the uterus had been dilated for relief of

sterility without result. There was no history of other instrumentation or of pelvic infection. Menstruation was normal and regular until 9 months before entrance, when it became excruciatingly painful and very profuse and of a brownish character much of the time.

Operation. Although there was a dark bloody discharge from the uterus, the cervical canal would not admit even the finest Hegar dilator. At abdominal hysterectomy the tubes and ovaries were found firmly plastered to the posterior surface of a uterus of double normal size which contained several small fibroids. The tubes were open at their fimbriated extremities.

Examination of the uterus after removal revealed cystic degeneration, stricturing and some pocketing throughout the length of the cervical canal, and stagnant dark liquid blood was present in the uterine cavity, evidently accumulated because of defective drainage.

In this patient without history or discoverable evidence of infection and no instrumentation other than dilation for sterility in her early married life, the etiology of the cystic degeneration and multiple firm strictures of the cervix is uncertain. Obstruction with backpressure of the retained secretion and retrograde menstruation rivals the more common infectious processes as the possible cause of the adhesions which held the patent tubes

Fig 8 Case 4. Low power photomicrograph of pocketed endocervix showing hyperplastic endocervical glands and metaplasia of columnar epithelium into squamous epithelium $\times 31$

and the ovaries to the posterior surface of the uterus

CASE 7. M. M. aged 38 years married 18 years entered Passavant Memorial Hospital September 30 1934. At the age of 22 years the patient had given birth to twins, delivered by forceps. A bilateral

thrombophlebitis developed in the puerperium and was persistently recurrent thereafter. When 27 years of age she had received a radium treatment, evidently an intracervical 2 hour 50 milligram application for a scar in the cervix. At the age of 32 years another child was born, a hard labor with bag insertion, followed by a recurrence of the thrombophlebitis

Fig 9 Case 4. Higher power photomicrograph of area of metaplastic epithelium which is also shown in Figure 8. $\times 95$

Fig 10 Case 4. Photomicrograph of endocervical epithelium under higher power (see Fig 8) showing deeply stained squamous cells replacing the columnar cells $\times 190$.

Cervical canal

Fig. 1. Case 9. Low power photomicrograph of endocervix. Impaction consisting of a stroma honeycombed by an multitude of glands and cysts gland spaces (see also text) $\times 9$.

At the time the patient came to me again more or less under my care thereafter because of pelvic discomfort and lacerations. She was also attended by an internist because of intractable colitis and recurrent fever. Menstruation became irregular at the age of 36 years, 2 years before entrance into the hospital. For 6 months the flow had been very profuse, greatly prolonged, and accompanied by severe dysmenorrhea. A persistent, dark brown, tarry discharge was present in the intervals.

Surgery was finally resorted to not only because of bleeding and progressive increase in the size of the uterus but also with the hope that operation might help the colitis. At exploration a varicocele nearly the size of one's wrist was found in the left broad ligament, a mass of veins one third as large was present on the right, one of them distended with an old thrombus.

The removed uterus was more than twice normal size and measured 6 1/4 inches in length. The external cervix was badly lacerated and frayed. Bisection revealed that the higher endocervix had undergone extensive cystic degeneration, the cervical canal being reduced to an exceedingly narrow distorted channel, barely admitting a probe. The constricted canal of the cervix passed over abruptly into a spacious uterine cavity. The body of the uterus presented a diffuse adenomyosis with massive thickening of the wall throughout (Fig. 12).

In the dilated pocketed lowermost portion of the uterine cavity we again found extensive metaplasia (Fig. 13). A rugged columnar epithelium was well preserved in some areas, in others it was more or less com-

pletely replaced by squamous cell metaplasia which often attained a depth of numerous layers. In the deeper uterine wall in this region, as well as elsewhere, there was extensive adenomyosis.

From clinical observation of the progress of this case as well as from study of the pathology encountered I am led to believe that stricture of the cervix with backpressure of retained secretions and menstrual blood was the cause of the adenomyosis of the uterus as well as the squamous cell metaplasia of the endometrium.

CASE 8. M. M. aged 49 years, unmarried, entered Passavant Memorial Hospital January 13, 1935. Regular menstruation during early years became more frequent and prolonged, changing to an irregular excessive flow at the age of 46. At the time of entrance there had been an amenorrhea for 7 months followed by profuse very dark bloody discharge which had persisted for 3 weeks.

Despite negative evidence on palpation of this virgin patient exploration of the uterus appeared necessary.

Operation. On dilation and curettage many pockets were encountered within the uterus and much succulent material was obtained. Because of multiple strictures and a suspicion of malignancy a vaginal hysterectomy was then resorted to. The tubes were found to be patent, but both tubes and ovaries were adherent and covered with innumerable superficial cystic nodules. The left ovary was largely replaced by a retention cyst. The uterus, opened after removal, was rigidly pockered and constricted both at the external os and at the internal os, with an intervening endocervical pocket the size of a walnut. The posterior cervical wall being thinned out and blemished. A polyp protruded into the cavity of the cervix. At the internal os the mucosa was rigid and corrugated, and the endometrial cavity above contained slimy dark fluid and innumerable polyps projecting into the lumen from the edematous moist mucosa (Fig. 14).

The microscopic structure of a broad based polyp at the right uterine horn revealed a papillary malignant growth.

Pathological diagnosis. Multiple strictures in a virgin uterus. Retention and back pressure of secretions with (1) endometrial polypoid development in the most uterine cavity, one growth in the right cornua presenting a picture of early papillary adenoma malignum, and (2) innumerable minute peritoneal cysts and slight adhesions of the tubes and ovaries.

In this case of obscure etiology occurring in a virgin patient obstruction and retention of secretions evidently predisposed to endometrial polyposis. One of the polyps presents a tendency to abnormal proliferation. Retro-

gradic spilling from the patent tubes may account for the adnexal pathology

CASE 9. A. G. aged 40 years married 16 years entered Passavant Memorial Hospital January 3 1933. There was a history of 2 births, one a forceps delivery with uncomplicated recovery after both. Two therapeutic abortions had been performed because of toxæmia of pregnancy. Subsequently in 1925 there was a pelvic operation with removal of adherent tubes suspension of the uterus and a vaginal trachelorrhaphy. Dysmenorrhœa present since puberty became more marked during the year following this operation. Premenstrual cramps of several days' duration became excruciatingly severe 6 months before she came to me. In 1933 and the menstrual flow established with difficulty became prolonged and profuse the history was typical of uterine obstruction.

At operation extensive adhesions were encountered throughout the abdomen being most marked in the pelvis. The right ovary was cystic and adherent, the left normal, the tubes were absent. The large uterus was buried in adhesions.

The uterus was opened after removal and it was found that amputation of the cervix at the previous operation had resulted in a snug fibrotic closure at the reconstructed external os, with some pocketing immediately above. In the vicinity of the internal os there was a ragged polypoid thickening of the endometrium with superficial necrosis. The involved area included nearly the entire circumference just above the internal os and was 1 centimeter in length. It apparently obstructed the lumen. A grossly recognizable wedge of invasion into the musculature suggested the possibility of malignancy. There was no dilation of the uterine cavity above (Fig. 15).

Fig. 12. Case 7. Massive uterus, 6½ inches in length with a lacerated frayed external cervix and a cystic badly strictured inner cervix terminating abruptly in a spacious uterine cavity; the body of the uterus presenting diffuse adenomyosis. (Two-thirds actual size.)

Fig. 13. Case . Photomicrograph of endometrium from lowermost portion of uterine cavity of uterus in Figure 12. Squamous cell metaplasia of columnar epithelium. X 100.

Fig. 14. Case 8. Virgin uterus with dense structures at the external os and the internal os, a dilated pocketed endocervix, accumulated fluid in the uterine cavity and endometrial polyp. Microscopic examination of the broad based polyp at the right uterine horn reveals a papillary adenoma malignum. (Two-thirds actual size.)

Microscopic study revealed marked cystic degeneration of the tissues in the region of fibrotic narrowing in the lowermost cervix. The tumorous growth above the internal os proved to be an early adenocarcinoma.

In this case a fibrotic narrowing at the external os apparently developed after a rather low operative repair of the cervix. Whether a polypoid growth occurred at the internal os because of retained secretions and a cancer developed in this region incident to and because of a benign tumorous obstruction or whether the malignancy occurred primarily and independently is a question. I assume that obstruction at the external os predisposed to the polypoid growth above whether the latter was primarily benign or malignant is problematical.

CASE 10. E. F. aged 27 years, married 7 years, never pregnant, reported for examination November 5, 1936. The uterus had been curetted 5 years previously and a year thereafter a Rubin test had been made. It was not certain whether the tubes were open.

When the patient came to me she complained of severe dysmenorrhea of 3 months duration. The uterus was well placed and no pathology was demonstrable on palpation, but a structure was found

in the cervical canal. It was dilated with much difficulty. A Rubin test demonstrated the patency of the fallopian tubes. The fibrous obstruction of the cervical canal was overcome by use of an electric cautery but the obstruction recurred repeatedly during the next several years. Dysmenorrhea of increasing severity became complicated by pelvic discomfort at other times and eventuated in a typical clinical picture of pelvic endometriosis.

At operation, September 15, 1934, the right ovary was found converted into a tarry cystic mass of four times normal size and extensive endometriomatous lesions were scattered elsewhere throughout the pelvis. The cervix was firmly strictured, the uterus in excellent upright position.

This patient evidently developed extensive diffuse pelvic endometriosis during the period that she was under my observation. The upright position maintained by the uterus throughout this time is a feature of interest. A persistently recurrent stricture of the cervix evidently created back pressure and retrograde menstrual spill into the pelvis and presumably was the cause of the endometriosis.

CASE 11. H. P. married, now 32 years of age has been under my care since a girl of 18, when she reported with a virulent gonococcal infection of the lower genital tract of 1 month's duration. The disease localized chiefly in the cervix and treatment was directed toward eradication of this focus upon subsidence of the active infection. The measures employed consisted of the usual procedures then in vogue—topical use of iodine and silver nitrate introduced on applicators, applied as gently as possible to the lowermost cervix, and later with failure of improvement to the endocervix at a higher level. The cervical canal became very tight and dilations were resorted to at various times. The stubborn persistence of a profuse creamy discharge led eventually to the intracervical use of radium. Occasional dilations of the cervix were required for the relief of distress from obstruction during the next 2 years but the symptoms gradually disappeared.

In 1925 a Rubin test revealed patency of the fallopian tubes. The uterus remained in an upright position, the adnexa apparently normal.

Two years later symptoms of cervical obstruction again recurred and the nasal tip cautery was applied to the endocervix under gas anesthesia.

There followed a period of 4 or 5 years of relative comfort. Menstruation was scanty but apparently without obstruction. Then the patient began to have scanty irregular menstruation with cramps and a discharge of dark menstrual blood. Pelvic distress increased and small fibroids were palpable in the uterus.

Operation April 10, 1934. Endometriomatous adhesions were encountered in the cul-de-sac. Firm bands held the sigmoid and rectum to the body of

the uterus, which was well placed and upright. The ovaries were small and healthy except for superficial endometriosis of the left.

The removed uterus contained multiple small fibroids and was atrophic. The cervix not more than half the usual size, was strictured at the external os, and in a pocket immediately above was $\frac{3}{8}$ cubic centimeter of fetid tarry blood. At the internal os was another stricture but no fluid was present in the endometrial cavity. The endometrium was atrophic. There were many small fibroids in the wall of the uterus, the largest the size of a plum.

This patient attended by me since she acquired a gonorrhoeal infection in her youth apparently developed a cervical stricture as the combined result of a severe infection and endocervical treatments directed toward eradication of the infection and relief of a persistently recurrent endocervical obstruction. Blocked drainage from the uterus may have been a factor in the etiology of the uterine fibroids and retrograde spilling of menstrual fluid was a probable factor in the development of pelvic endometriosis which occurred despite the upright position of the uterus.

CASE 12 B C Six years ago at the age of 27 this patient, married two and one half years, reported to a physician for examination because of a missed menstrual period and suspected pregnancy. An erosion was found and an electric cautery knife was applied to the cervix.

When first seen by me 9 months later there had been persistent amenorrhoea since the time of cauterization. The cervix was closed tightly the body of the uterus was soft and several times normal size.

At operation the cervix was found to be completely strictured the entire uterus converted into a soft boggy mass, the walls of the cervix thinned out to a thickness of a few millimeters. Two hundred cubic centimeters of dark liquid blood escaped upon opening the cervical canal.

The fallopian tubes were tested for patency 3 months later and were found to be obstructed but the obstruction was readily overcome. Sterility has persisted but pelvic discomfort which caused considerable distress for a year or 2 has gradually disappeared.

Stricture obstruction of the cervix required repeated dilations during the first 3 years following drainage of the hematometra but the canal has now remained patent for several months without dilation, although occasional use of a Hegar dilator is still necessary. Menstruation is scanty and there is evidence of an impending premature menopause at the age of 33 years.

Other cases of hematometra occurring in early married life have been encountered. It

Fig. 15 Case 9 Diagrammatic illustration of uterus with a reconstructed cervix pocketed above, incidental to repair. There was gradual development of a tight external canal, with back pressure retention. Early adenocarcinoma just above internal os. (One half actual size)

is not a rare complication following avulsion of the cervix during delivery. Re-establishment of a satisfactory canal is exceedingly difficult unless corrected within a few months. Sterility is the rule. Retention of menstrual blood with complicating pelvic pathology has made surgical intervention necessary in the majority of cases which I have encountered.

SUMMARY AND CONCLUSIONS

1 The frequency of cervical strictures merits its repeated emphasis. They are of common occurrence in the practice of everyone concerned with pelvic diseases of women.

2 The various therapeutic procedures employed in treatment of lesions of the cervix are more important than any other factor in the etiology of cervical obstructions. Endocervicitis is also important in the etiology and in the majority of cases of serious stricture there is a history of an inflammatory process as well as of instrumentation. It must not be assumed however that absence of a history of infection or of instrumentation invariably gives assurance of a patent cervical canal and adequate uterine drainage. Strictures of the worst kind are encountered in virgin patients and in others in whom there is no discoverable predisposing factor.

3 Fibrotic constriction of the cervical lumen is much more serious than simple obstruction by adhesions. If drainage is not free

pocketing of the cervix may occur immediately above the fibrous obstruction

4 A metaplasia of the columnar epithelium into squamous epithelium has been found in the roughened pocketed *endocervix* above cervical strictures. A similar metaplasia has occurred in the pocketed *endometrium* above a cervical stricture. Irritation from retained secretions may be a factor in stimulating the metaplasia. (The question arises as to whether the seepage of irritating retained secretions from the pocketed cervix may be a factor in the production of leucoplacia of the external cervix.) We find here in the presence of leucoplacic squamous cell metaplastic tissue bathed in retained menstrual fluid and debris, a possible explanation of the frequent incidence of squamous cell cancer of the *endocervix* and adjacent *endometrium*.

5 Tumorous nodulations of the *endocervix* and lower uterine segment are a less common cause of uterine obstruction.

6 The effects of damming back of uterine secretions and menstrual blood may be far reaching—perhaps important in the etiology of endometrial polyps, adenomyosis of the uterus, pelvic endometriosis and back pressure inflammatory processes in the pelvis. The relationship of obstructive retention to the development of intra uterine cancer is a problem which merits further study.

7 If my individual experience is a criterion it will eventually be regarded as a surgical sin to use radium or make repeated endocervical topical applications, or apply the cautery within the cervical canal or amputate the cervix of the uterus, or even administer expectant care to a patient with notable endocervical disease without prolonged and attentive observation thereafter directed to the maintenance of patency of the cervical canal. Our thoughts have been too little concerned with the lumen of the uterus and the importance of free uterine drainage.

THE PREPERITONEAL LAYER—ITS GYNECOLOGICAL APPLICATION

JOSHUA WILLIAM DAVIES, A.B. M.D. F.A.C.S. NEW YORK, NEW YORK.
From the Department of Anatomy, Columbia University Medical School, and the Women's Hospital, New York.

SUPERFICIAL to the peritoneum there is a definite layer of fibro areolar tissue containing varying quantities of fat, smooth muscle and elastic tissue. It is this structure which disorients the student about to make an incision into the abdominal cavity, especially in the midline.

Various names have been given to the layer. The term fascia endo-pelvina is confusing unless one adopts the classification in which two systems of fascia are recognized: the one a dense supportive tissue applied to voluntary muscle and the other an areolar fascia applied to abdominal and pelvic organs. Gallaudet called this layer the subperitoneal fibro areolar layer due to the fact that it is found beneath the peritoneum when the operator is working within the abdominal cavity. Others call it the extraperitoneal layer which in itself is incomprehensive because the muscular as well as the subcutaneous and skin layers are likewise extraperitoneal. The Germans refer to the layer as *Bindegeewebe* i.e. connective tissue because it is applied to and binds the various structures of the abdomen and the pelvis. The term preperitoneal accurately localizes the structure in the abdominal wall.

In the abdominal region the layer is closely related to the peritoneum as it ensheathes the adrenals, kidneys, ureters, vas colon, vessels and nerves but as it extends into the false and true pelvis it ensheathes the rectum, vagina, bladder, seminal vesicles and the prostate; it is apparently not so intimately connected with the peritoneum. It does however continue to lie between the peritoneum and the transversalis fascia which in the pelvis is called the supra-anal fascia. During youth the general tonicity and the deposit of fat aids in maintaining the supporting function of this structure but illness with the absorption of fat or old age with the diminishing of general tonicity predisposes to abdominal and pelvic relaxations. During the child-bearing period nature attempts to restore the

relaxed or lacerated structure by increasing the proportion of involuntary muscular and fibrous tissue thereby postponing the fatiguing symptoms of prolapsus until the support of pelvic congestion is removed by the menopause.

Considerable discussion exists as to the nature and the origin of the structure surrounding the vagina, uterus, bladder and the rectum. Each of these structures must perforate the musculo-fascial layers of the pelvic outlet to function normally and consequently their covering must fuse with the transversalis or supra-anal fascia covering the superior surface of the levator ani muscle. To assume that distensible organs are covered with a definite restraining structure such as that covering voluntary muscle is highly improbable but by beginning in the abdominal wall and tracing the preperitoneal tissue around the adrenals and kidneys into the false and true pelvis in a single sheet one can more readily understand the consistency and function of the structure without the use of a microscope. Histologically proving a structure does not interpret its relationship.

Pelvic surgeons are familiar with the terms pubocervical, paravesical, paravaginal, para-rectal, presacral, uterosacral, lateral ligaments of the vagina and pillars of the rectum but many fail to see that they are merely thickenings of the preperitoneal layer especially so around the vessels and nerves as they course from the lateral pelvic wall to the pelvic organs. It was because of a desire to comprehend this structure that this study was carried on.

In Figure 1 the peritoneum has been removed from a male specimen thereby exposing a continuous layer of preperitoneal tissue which extends from the abdominal into the pelvic region. It will be noted that the ureter, abdominal vessels and nerves are ensheathed and supported by this structure. As they are traced to the rectum and the bladder it is noted that the same layer envelops them.

Fig. 1

thereby protecting and aiding in maintaining their position. On the left the layer of preperitoneal tissue has been incised and retracted to expose the transversalis fascia covering the psoas muscle. Anteriorly retraction of the layer exposes the bladder and seminal vesicles. In the region of the seminal vesicles the involuntary muscular fibers of the layer are increased and probably aid in compressing the seminal vesicles during ejaculation since they are devoid of a muscular coat.

After removal of the coccyx and the lower segments of the sacrum preparatory to the removal of the rectum for carcinoma it is necessary to incise the preperitoneal layer before the rectum can be exposed. This layer has been called the presacral layer. In the same manner it is necessary to incise the preperitoneal layer to expose the seminal vesicles, prostate or bladder. With the Latsko cesarean section the layer is divided by blunt dissection and the bladder is retracted to expose the anterior surface of the uterus.

From the anterior surface of the rectum the layer can be traced anteriorly to the bladder. An incision in this region will expose the continuation of the transversalis fascia on the superior surface of the levator.

Fig. 2

To facilitate a comprehension of the structure in a female let us interpose the vagina and the uterus between the rectum and the bladder and at the same time perforate the levator and its fascial coverings, thereby establishing a communication with the vulva. The vagina and the uterus will then be ensheathed by the same layer as the rectum and the bladder from which it receives support, and especially from the thickened strands of involuntary muscular and fibrous tissue contained therein.

In Figure 2 the peritoneum on the right side of a female pelvis has been removed thereby exposing the preperitoneal layer about to be studied. By blunt dissection the layer was mobilized from the lateral pelvic wall as a wide sheet thereby exposing the continuation of the transversalis fascia into the false and true pelvis. It is noted that this procedure carried with it the contained rectum, vagina, uterus, and the bladder.

In Figure 3 the peritoneum was separated from the cul-de-sac, thereby isolating a distinct layer of preperitoneal tissue which lines the pelvis. Anteriorly within the layer is the bladder posteriorly the rectum while medially are the vagina and the uterus. The blood supply to the rectum comes from the superior and middle hemorrhoidal vessels which traverse this structure and except for the missing peritoneal covering is a structure not unlike a mesentery. The blood supply to

Fig. 3.

the bladder is from the superior middle and inferior vesical vessels which run in the preperitoneal layer from the internal hypogastric trunk to the lateral wall of the bladder. This organ can be then considered to be the center of a sling composed laterally of blood vessels and nerves contained within the preperitoneal layer.

The component parts of the uterus and the vagina, the muellerian ducts develop in the layer midway between the rectum and the vagina where they are supplied by branches from the internal hypogastric vessels. As they approximate each other and fuse, the uterus and the vagina are formed. They are likewise covered by a layer of thin preperitoneal tissue and are supported laterally by its vascular supply the lateral mesenteroids of the vagina. This term is used because the blood supply to the individual muellerian duct is not unlike a mesentery of the intestine except that it is devoid of a peritoneal covering.

Stretching laterally and posteriorly from the uterus is the familiar uterosacral ligament which is composed principally of involuntary muscular strands and fibrous tissue. However after the cul-de-sac is stripped of its peritoneum it is noted that the uterosacral ligament as such is not a distinct free muscular strand like the round ligament but it is the upper free margin of a distinct plane of tissue lining the true pelvis. That portion of

Fig. 4.

the plane distal to the uterus is attached to the lateral wall of the vagina and may be called the vaginosacral ligament or more descriptively the lateral mesenteroid of the vagina.

In Figure 4 the uterosacral ligament and the vaginosacral ligament have been incised proximodistally to its distal boundary the supra anal fascia.

In Figure 5 that portion of the preperitoneal tissue distal to the cul-de-sac is shown. The posterior portion depicts the divided uterosacral and vaginosacral ligaments there by exposing the preperitoneal layer covering the supra anal fascia between the rectum and the vagina. This layer contains branches from the middle hemorrhoidal artery which are distributed to the posterior wall of the vagina.

Fig. 5.

It has been called a pillar of the rectum because of the definite hypertrophy noted during operations for the cure of a rectocele. Structurally it is the rectovaginal mesenteroid and when overstretched or lacerated by child birth the rectum is permitted to bulge the lower third of the posterior vaginal wall.

Anterior to the vagina the vaginosacral ligament becomes continuous with the lateral vesical ligament which contains the vessels and nerves supplying the bladder. It has been separated from the lateral wall of the vagina and retracted anteriorly to show a structure similar to the rectovaginal mesenteroid which extends from the pubis to the urethra and from the urethra to the cervico-uterine junction. This structure is however rather intimately attached to the distal surface of the bladder and when relaxed or lacerated by childbirth throws an additional stress against the anterior wall of the vagina, which if similarly relaxed will result in the formation of a cystocele. It must be understood that the covering of preperitoneal tissue on the anterior and posterior walls of the vagina is of little value in the prevention of a cystocele or a rectocele but the rectovaginal mesenteroid and the pubocervical ligament are distinctly efficient.

RETROVERSION

In the upright posture the uterus appears to be suspended by the uterosacral ligaments, while traction by the round ligaments and intra-abdominal pressure force the fundus anteriorly. Utilization of the round ligaments is more efficacious than the plication of the uterosacra for the operative relief of this displacement. If however there is a tendency to prolapsus and a relaxation of the walls of the vagina insufficient for repair the plication or transplantation of the uterosacra will be of value.

PROLAPSE

During the third and fourth decades of life a retroverted uterus is able to withstand the stress of intra-abdominal pressure due to the support given to the uterus by its lateral attachments however with advancing years and a concomitant general relaxation the

lateral support permits a sagging of the uterus. An operation for retroversion together with a shortening of the uterosacra and a tightening of the lateral ligaments will relieve the condition. However as is usually the case other plastic surgery is needed below therefore the plication of the lateral uterine ligaments as suggested by Alexandroff is sufficient without opening the abdomen from above. The more extensive prolapse can be relieved by a vaginal hysterectomy. To obtain a deep vagina and at the same time increase the tonicity of the pelvic outlet the vault of the vagina should be closed from side to side thereby tightening the sling of the vaginal mesenteroids, which support the vagina laterally. This procedure while improving the tonicity of the vault will relax the uterosacral and the pubocervical ligaments unless definite steps are taken to unite them before the vault of the vagina is closed.

ENTEROCELE

A relaxation of the pararectal connective tissue together with a deep cul-de-sac, permits a herniation between the vagina and the rectum which is evidenced as a bulging of the posterior wall of the vagina above the usual rectocele. The approximation of the uterosacra from side to side will obliterate the cul-de-sac and act as an efficient barrier to a recurrence if at the same time other necessary vaginal repairs are done.

RECTOCELE

Prolonged stretching of the vagina tends to prevent proper involution of the vagina and the surrounding structures particularly the rectovaginal mesenteroid which acts as an accessory barrier to pressure from the rectum against the lower third of the vagina where the stress is more direct. The usual operative procedure in which the vagina is mobilized posteriorly and a triangular area of the relaxed tissue is removed together with a repair of the pelvic floor is often times sufficient. If however the rectovaginal mesenteroid is first isolated and plicated in the midline or transplanted above the crest of the rectocele as described by Dr. George Gray Ward a more defensive barrier is established. An at

tempt should be made to plicate or reattach this structure medial to the blood vessels therein so as not to alter the vaginal blood supply

CYSTOCELE

Prolonged stretching of the vagina together with the eversion of the anterior wall by the descending head tends to prevent proper involution of the anterior wall of the vagina and also the pubocervical ligament. Mobilization of the anterior wall of the vagina and the removal of the relaxed tissue restores the wall of the vagina and improves the tonicity of the lateral ligaments of the vagina which in turn fairly satisfactorily relieves the cystocele if however, the relaxed or retracted pubocervical ligament, which is closely applied to the bladder, is plicated and restored in the midline the tonicity of the bladder will be restored through the increased tension of the lateral vesical ligaments. To one's surprise the removal of the redundant vaginal tissue will appear unnecessary, other than for the relief of the relaxed vaginal wall. Dr William T. Kennedy has, likewise, repeatedly carried out this procedure. After a complete hysterectomy has been done the lateral ligaments of the vagina should be approximated in the midline and an attempt should be made to approximate the uterosacral and pubocervical ligaments over the vaginal vault particularly if there is a concomitant cystocele. This procedure definitely restores the tonicity to the floor of the bladder.

No reference has been made to the repair of the pelvic floor which must necessarily be repaired, if the efficiency of the lateral ligaments of the vagina and the musculo-fascial layers of the pelvic outlet are to be utilized most effectively.

CONCLUSIONS

1 The pelvic cavity is lined by a layer of preperitoneal tissue similar to the lining of the abdominal cavity

2 As the kidney is held by preperitoneal tissue, likewise are the pelvic structures supported

3 Prolonged distention of the vagina causes relaxation of the vaginal walls, the pubocervical ligament, and the rectovaginal mesenteroid

4. Following a complete hysterectomy, a deeper vagina can be obtained by closure of the vault from side to side rather than anteroposteriorly

5 A small cystocele can be treated from within the abdominal cavity by tightening the pubocervical ligament, or by reattaching it to the uterosacral ligament following a complete hysterectomy

6 Rectocele follows injuries to the posterior wall of the vagina and to the rectovaginal mesenteroid

7 Prolonged stretching of the vagina may relax the anterior wall as well as the pubocervical ligament which is rather intimately attached to the inferior surface of the bladder

8 Reconstruction of the pubocervical ligament in the midline, increases the support of the bladder through its lateral ligaments and makes the removal of the relaxed vaginal tissue appear to be an unnecessary procedure, other than to aid in the restoration of a normal contour

9 A granulomatous infection of the posterior portion of the vulva or the posterior wall of the vagina may extend to the rectum by way of the lymphatics in the rectovaginal mesenteroid and cause a rectal stricture about 3 centimeters from the anus

DIVERTICULA OF THE DUODENUM

HAROLD C. EDWARDS, F.R.C.S. (Eng.) LONDON, ENGLAND
 Surgeon, King College Hospital, Honorary Professor, Royal College of Surgeons

IN a woman of 80 dead of apoplexy Chomel found a duodenal pouch containing 22 stones. This case, published in 1710 is the first reference to pouching of the duodenum to be found in the literature. The sac is described as an extension of the membranes *vers le haut de cet intestin*. Morgagni refers to Chomel's case in his *De Sedibus*. The former thought the stones were gall stones, as the sac appeared to communicate with the common bile duct. In Morgagni's opinion these stones had passed through the bile duct and for some reason or other had been detained in the duodenum and had caused a diverticulum.

Morgagni mentions a case of diverticulum of the rectum and gives a full account of diverticulum of the duodenum 2 inches beyond the pylorus, discovered postmortem in the body of a man, also dead of apoplexy. The English translation (1769) of Morgagni's description runs thus

a kind of cellule, not very protuberating, but big enough to admit a finger surrounded with no coat but the external one of the intestine yet having not the least traces of any present, or past, ulceration in that part, as indeed there were not in the stomach, or the whole intestinal tube

In 1796 Rahn describes what was presumably a duodenal diverticulum secondary to an ulcer occurring in a woman of 22 who died from emesis. In 1815 Fleischman described 3 cases, all intimately related to the pancreatic and common bile ducts. Fleischman suggested as a cause frequent distention with food drink, or air. He also made reference to diverticula in the large bowel.

Habersohn in 1857 commented on the rarity of diverticula of the duodenum compared with those of the colon. He regarded them all as hernial protrusions of the mucosa through the muscular coat.

In the same year Harley described a pouch midway between the pylorus and ampulla of Vater in a man of 87. It contained a gall stone measuring 3 inches by 3¼ inches, and

weighed 450 grains. The gall bladder was thick and shrunken and buried in adhesions, while the common bile duct was dilated.

The first comprehensive survey was made by Roth in 1872 who after the study of 5 personal cases, concluded that diverticula of the duodenum are exclusively of the "false" variety they do not get larger than a pigeon's egg and are usually empty. "False" is used, apparently as opposed to "congenital."

In 1884 Turner contributed the first detailed description of the association between duodenal ulcer and duodenal pouches, and mentioned three varieties.

In 1893 Perry and Shaw made an extensive study of the postmortem records of Guy's Hospital describing 13 cases of diverticula of the duodenum. These they subdivided into (a) non-inflammatory and (b) depending upon operation or outside traction. These authors formed the opinion that the development of the non-inflammatory pouches depends upon abnormally high pressure inside the duodenum and their views in this connection will again be referred to.

The article of Perry and Shaw is the foundation stone of our present knowledge of the condition and those interested in duodenal diverticula can do no better than to commence their study with this article.

Other publications follow in more rapid sequence those of Fischer and Rolleston in 1900 of Keith in 1910 Baldwin in 1911 Moynihan in 1912 and of Linsmayer in 1914. This last work is a second landmark. Linsmayer's observations are based upon post mortem material. He expressly set out with the intention of investigating the condition, and was surprised to find 45 examples of the simple (non-inflammatory) type and 4 of the secondary type in 1,367 postmortem examinations.

In 1915 appeared the first recorded case diagnosed by X-ray and verified by operation (Forssell and Key). During the war years, apart from a preliminary observation in 1916

on the X ray diagnosis by Case little of importance occurred. The year 1920 however, was epochal. Papers by Spriggs and Marxer in England, Case in America, and Clairmont and Schintz in Germany described in detail the X ray appearances of duodenal diverticula. Wilkie's well known publication followed in 1921. Many excellent articles most of which are referred to in the following pages appeared during the last decade and a culminating point was reached in 1930 when Otto Hahn published an extensive "Review of the Literature of Duodenal Diverticula."

CLASSIFICATION OF DUODENAL DIVERTICULA

"Many instances of congenital intestinal diverticula of the duodenum have been recorded particularly in the second portion. Now that screen examinations after a bismuth meal are so constantly made duodenal diverticula have ceased to be looked upon as great rarities." This quotation from a recent exhaustive treatise illustrates the existing confusion with regard to the etiology of duodenal diverticula. The author has found that the vast majority of diverticula in this portion of the intestine are divided among the acquired hernial (or primary) type and those secondary to ulcer. The remainder are traction diverticula and anomalous forms. True congenital diverticulum—i.e., a diverticulum present from birth and identical in structure to the intestine from which it arises,—is a condition of exceptional rarity in the duodenum. This is a matter for surprise for one would expect the duodenum to be a fertile source in view of the development of the pancreas from it.

The possibility of there being a congenital factor in the etiology of the hernial type of diverticulum is conceded (although not supported), but this does not entitle this type to be called congenital diverticula for their morbid anatomy and their age incidence are diametrically opposed to the concept of a congenital status.

MATERIAL

The following account of acquired diverticula of the duodenum is based on the examination of the following material:

X rays 31 cases of which 26 are probably of the hernial type (primary acquired diverticula) and 5 of the secondary type. Of these, 3 are secondary to ulcer and 2 due to traction.

Pathological specimens 4 specimens of diverticula of the hernial type 7 specimens of diverticula secondary to ulcer.

Operation cases Three diverticula were exposed at operation 1 of which was secondary to an ulcer, and 1 due to traction by an adherent gall bladder. The third was removed intact (Fig. 7).

THE RADIOLOGICAL STANDPOINT

Incidence. During the 7 year period 1925-1931, inclusive, X rays have provided 31 examples of duodenal diverticulum. The total number of examinations made during this period was 4,631, so that in this series the percentage incidence is 0.67 per cent. The incidence of these cases in each year is as follows:

1925	1 in 521 X rays—0.19 per cent
1926	1 in 580 X rays—0.17 per cent
1927	1 in 630 X rays—0.16 per cent
1928	6 in 653 X rays—0.92 per cent
1929	6 in 612 X rays—1.47 per cent
1930	7 in 781 X rays—0.90 per cent
1931	6 in 854 X rays—0.70 per cent

The jump in incidence from the 0.2 per cent (approximately) of the 3 years 1925, 1926 and 1927 to 1.0 per cent (approximately) of the succeeding years coincides with the remodelling of the routine X ray technique in the early part of 1928, the chief added features being (1) screening of all cases (2) examination in the oblique position. In the first 3 months of 1928 before the technique was thus altered 1 case only was reported, but during the remaining 9 months 5 cases were reported. There can be no doubt that before 1928 cases of diverticula were being missed during examination and the percentages for these years do not represent the true incidence of the condition. If the years 1929, 1930 and 1931 are taken the figures are 22 cases in 2,247 X ray examinations, or a shade under 1 per cent. This compares very closely with the figures of Andrews, 26 cases in 2,200 examinations (just over 1 per cent) and Spriggs and Marxer, who found, in their first series 10 cases in 1,000 X rays (1.0 per cent). Case describes 85 cases in 6,847 X ray examinations (1.24 per cent). Spriggs and Marxer in 1925 however gave a

further series of 38 cases in 1 000 X ray films an incidence of 3.8 per cent while Cryderman found 45 cases in 770 X ray examinations (5.85 per cent).

Five of the author's 31 cases were definitely of the secondary type 3 being associated with clinical and other radiological evidence of a duodenal ulcer and 2 being in all probability traction diverticula. Another case in which barium entered the hepatic ducts, and which will subsequently be described is not included in these figures as the exact pathology is undetermined. Five cases in which some doubt existed are also excluded. The figures in tabular form are thus:

Total cases	31
Primary	26
Secondary	
With ulcer	3
Traction	2

These figures probably bear no direct relation to the relative incidence of the primary type and the ulcer type. It is not always possible even after screening and taking oblique roentgenograms to detect an ulcer diverticulum. One sees a fixed deformity of the duodenal cap but a diverticulum though present may be too shallow to show up clearly or its position may be such that it does not show in relief. Thus in Case 32 operation revealed a well defined pouch on the anterior wall of the duodenum that was wholly unsuspected by the radiologist (Fig. 1).

As opposed to the ulcer diverticulum primary diverticula show up readily in a thorough X ray examination. Confusion exists in some cases between a primary diverticulum and a dilatation of the common bile duct. It may be in fact impossible to distinguish between these two conditions—they may be associated in the same case—on radiological evidence alone.

Contrary again to the ulcer diverticulum the primary type is detected more easily radiologically than at operation. The latter all arise from the second and third parts of the duodenum and many lie behind or are overlapped by the pancreas. It is sometimes only with difficulty that a diverticulum can be found at operation even when its presence is known beforehand and a definite search is made.

The same applies to postmortem examination at which diverticula will easily be missed unless the examiner is alive to the possibility of their occurrence and opens the duodenum throughout its whole length, so that he may examine its concave margin carefully from the mucous membrane side.

Radiological appearances. Duodenal diverticula are seen as smooth barium filled pockets persisting at a 3 hour or 6 hour roentgenogram. Unless large and well defined a pocket in the first part of the duodenum associated with an ulcer will not be revealed. The duodenum may show marked deformity—often the shamrock-leaf deformity described by radiologists as typical of duodenal ulcer—but no definite diverticulum. Furthermore, the pockets secondary to ulcer are in most cases shallow and wide mouthed and there is no retention of barium in them. They empty with the duodenum.

On the other hand in Case 32 a well marked ulcer diverticulum was seen without difficulty at operation (Fig. 1) but was unsuspected at X ray examination. It is frequently impossible to establish the exact point of opening of a diverticulum into the duodenum, and a differential diagnosis between ulcer diverticulum and the primary type cannot readily be made. If however peristalsis is seen in the wall of the diverticulum it is certain to be of the ulcer type. Diverticula of the second part of the duodenum, the commonest site for diverticula of the primary type, are readily seen by X ray and if the routine described above be followed will rarely be missed.

Figure 2 is selected as a typical example. In this case the colon was also the seat of multiple diverticula. A partly filled but well defined pouch in the concavity of the duodenum is shown. It empties into the second part of the duodenum and there was no retention of barium after 3 hours. The question of barium retention after the duodenum is empty must be carefully studied as only in such cases can the diverticulum be suspected of causing symptoms.

Diverticula of the horizontal and ascending parts of the duodenum are rarer and not so readily seen. This latter point may in fact,

be a partial explanation of the rarity of this finding as compared with diverticula of the second part.

The oblique position for examination is of especial importance in revealing diverticula near the flexure, and increasing frequency of incidence of diverticula in this situation during the past 3 years is due in part to the adoption of this routine.

In diverticula of the horizontal portion the mouth of the diverticulum is on the concave surface of the duodenum and the sac in the great majority of cases passes upward in relation to the pancreas. With this dependent drainage, the barium may not enter the diverticulum, or if it does so remain for so short a period that it escapes detection. In the rare cases in which the diverticulum has increased in size so much that it hangs downward its presence is readily detected, for stasis will always be present.

Buckstein, writing in 1927 and before oblique views were adopted as a routine recommended a duodenogram for showing up doubtful cases of diverticula near the flexure in which position, he states, they may be confused with an ulcer crater on the lesser curvature of the stomach. A radio-opaque duodenal tube the first 10 inches of which has many small perforations made in its wall is swallowed until the duodenojejunal flexure is reached, as determined by examination under the screen. A thin suspension of barium is then slowly injected and an X ray is taken immediately, so that an outline of the duodenum alone is obtained.

The oblique view has in our opinion however, obviated the necessity for this elaborate technique, and the print published by Buckstein is not sufficiently convincing to warrant a trial of this method.

Traction diverticula are rare and difficult to distinguish radiologically from other types. Points to be noted in arriving at the diagnosis are the shape and fixation of the shadow. The diverticulum may not have a spherical rounded appearance but a somewhat conical outline. It will be fixed to neighboring viscera.

The most frequent sites for traction diverticula are in the gall-bladder region and at the

flexure, where occasionally the intestine may become caught up by perigastric fibrosis around an ulcer of the lesser curvature of the stomach.

Identical X ray appearances, however, may be caused by secondary inflammatory changes occurring in the primary form of diverticulum.

Pitfalls in X ray diagnosis. Occasionally extra luminal flecks of barium in the first and second parts of the duodenum remaining after emptying of the gut will rouse suspicions of the presence of a diverticulum. A second examination should be made in such cases, and attention in screening carefully focused upon these abnormalities. Such shadows in the first part may be due to the presence of a small ulcer crater and in the second part to barium getting into a dilated common bile duct or to the anatomical variation of the opening of the bile and pancreatic ducts into the duodenum. In cases in which a smooth rounded appearance of the shadow cannot be obtained on palpation of the duodenum, a confident diagnosis of diverticulum cannot be made. Five such cases occurred in the series of X ray plates under review (not included in the 31 cases of diverticula).

Anatomical variations in the duodenum may give rise to some difficulty in the diagnosis. Heacock describes a case of pseudo-diverticulum due to a fixed redundancy of the duodenum without any defect in the wall of the intestine. This condition was confirmed at operation. Larimore also draws attention to this appearance. It is a degree of that duplication of the duodenum described first by Wilkie. In these cases, the longitudinal plica, which terminates at the ampulla, stands out as a well marked fold dividing the second part of the duodenum vertically into two compartments. The condition is undoubtedly a minor variation of complete duplication of the duodenum described by Calder, in which two definite tubes existed. Fairland described such a duplicature of the whole tract from the pylorus to the cæcum. Wilkie also describes an infolding of the duodenal wall in the transverse axis giving rise to a ring like constriction. He thinks it is a mild form of the duodenal stenosis met with occasionally in children.

These appearances are readily distinguishable from those of a diverticulum by careful screening especially in the oblique view. The normal 'feathery' appearance of the duodenum in duplicature is retained without interruption.

Other departures from the normal topography of the duodenum should not give any difficulty. Differences in shape, the enlarged bulb due to an annular pancreas, abnormal positions and ileus are not readily to be confused. Shadows occasioned by other things, such as gall stones and pancreatic stones, will be excluded.

Unquestionably the most important procedure in X-ray diagnosis is the screening operation—palpation of the duodenum under observation. It transcends in importance the fixed roentgenograms with which the clinician is furnished and outweighs any conclusions that may be deduced from these impressions.

PRIMARY ACQUIRED DIVERTICULA OF THE DUODENUM

Of the author's 5 specimens (4 postmortem and 1 operation) 4 are examples of single diverticula arising in relation to the entrance of the common bile duct (perivaterien). In the fifth 2 diverticula are present arising from the transverse part of the duodenum.

Specimen 1. The specimen illustrated in Figure 3 was obtained postmortem from a woman of 77 years, who died following an operation upon a carcinoma of the colon (Case 6). Diverticula were present also in the large intestine.

The duodenum has been opened by dividing the anterior wall in the midline. Bristles have been placed in the common opening of the common bile and pancreatic ducts in the ampulla of Vater and in the opening of the duct of Santorini above. The major ampulla is unduly prominent. Its right margin is continuous with a transverse plica which forms the anterior lip of a wide mouthed diverticulum, and which then continues as a well defined transverse plica on the posterior and right lateral wall of the intestine.

The direction of the diverticulum is to the left, and slightly upward and backward, following exactly the same course as the common bile duct through the duodenal wall. On the reverse side of the specimen, the diverticulum could be seen as an ill defined bulge of the duodenum into the pancreas. It is separated from the latter by a narrow interval filled with loose areolar tissue, and the pancreas

could be freed by blunt dissection. The mucous membrane lining the pouch is smooth and free from rugae, but otherwise normal. A microscopic section of the wall at the fundus of the diverticulum shows only a small number of muscle fibers lying in a thin wall of fibrous tissue. A large vessel is lying within the wall.

Specimen 2. The specimen illustrated in Figure 4 is from a dissecting room subject. The pancreas has been removed except for a small portion of the head in immediate contact with the concavity of the duodenum. This has been dissected free, and turned upward. Between the pancreas and the common bile duct there is a large diverticulum. This is flask shaped, but not completely regular in outline. This fact is due in part to irregular shrinkage following prolonged preservation in a formalin solution. The wall of the diverticulum is as thin as tissue paper and transmits light equally well. Microscopic sections show the wall to consist of a very thin layer of fibrous tissue, with no trace of a muscle coat. The mucous membrane has been partially destroyed by autolysis.

When the duodenum was opened, it was found that the relation of the mouth of the diverticulum to the ampulla of Vater was similar to that in Specimen 1.

Specimen 3. The specimen illustrated in Figure 5 is from a dissecting room subject, a man of 79. The duodenum is an unusually large one, but no obstruction was present. The walls are of about normal thickness, there being no evidence either of thinning from passive distention, or thickening from hypertrophy. A small portion of pancreas remains attached to the duodenum, and is retracted forward by a hook. Between this portion of the pancreas, and above and in front of the common bile duct, is a large diverticulum. It has been packed out with cotton wool, but before this was done was lax and collapsed. The wall is extremely thin and readily transmits light. The mucous lining is smooth, and contains no rugae. The diverticulum in the recent state lay posterior to the duodenal margin of the head of the pancreas from which it was separated by a thin layer of areolar tissue.

The relation of the mouth of the diverticulum to the ampulla of Vater is as in Specimens 1 and 2.

Specimen 4. This specimen, illustrated in Figure 6 was obtained in the dissecting room from the body of a man aged 71. To obtain the illustration, the specimen was suspended, and viewed from above and behind. A portion of the head of the pancreas remains attached. Two small diverticula are present, opening from the transverse portion of the third part of the duodenum, the second one (nearest the "camera") being at the junction of this part with the ascending part of the duodenum. The double row of blood vessels supplying this part of the duodenum, to be described in full subsequently is clearly seen.

The outline of this diverticulum is indicated by an interrupted line, as it was removed with the

intestine before the drawing was made. Whole serial sections were cut, one of them passing through the maximum girth of the diverticulum.

The double row of blood vessels supplying the duodenum to which a detailed reference will be made later is clearly seen, one row lying posterior and the second anterior to the midline. The latter is represented by the thick interrupted line in the illustration.

In each case, the opening of the diverticulum is to the posterior side of the midline, in relation to one of the posterior row of blood vessels. This is very clearly shown in the smaller diverticulum, for the section through its base has cut through an artery which ran into the wall of the diverticulum and is well shown in the section.

Microscopic appearance. A section passing through the maximum diameter of the diverticulum which is completely devoid of a muscular layer shows that the muscle of the duodenum ceases abruptly at the mouth of the diverticulum and there is no suggestion of it being carried along in its wall. The muscle in the angle between the intestine and the pouch appears to be a little thicker than elsewhere in the duodenum as though it had undergone a certain amount of hypertrophy. A large artery can be seen between the submucous layer of the diverticulum and the muscularis of the duodenum and its companion vein is seen as a long narrow chink. This artery corresponds with the one cut across, as shown in the illustration. The diverticulum consists of an extremely thin layer of fibrous tissue covered with serosa, and lined by mucous membrane the latter is thin and contains no rugae. No pancreatic tissue or Brunner's glands are present.

Specimen 5 (Fig. 7). Perivaterien diverticulum removed at operation from a woman of 54 years. It is a thin walled sac, devoid of a muscular coat and having a cubic capacity of 14.5 cubic centimeters. The radiological appearance is shown in Figure 8. The patient complained of abdominal pain, with occasional sickness, and a distressing amount of flatulence after meals. The history extended back for some 9 or 10 years and the symptoms had become progressively worse despite periods of treatment elsewhere for gastric ulcer. Six years before admission appendectomy had been done with no relief. No other cause for the symptoms was demonstrated, and removal of the diverticulum resulted in a complete cure of the distressing flatulence. The patient still complains of occasional pain, but this has very greatly improved, and 11 months after operation her weight had increased from 7 stone 6 pounds to 8 stone 10 pounds.

A typical primary duodenal diverticulum is thus a thin walled sac opening into the bowel by a wide mouth. Except in exceptional instances it rarely exceeds the size of a golf ball. It is rounded in shape, as opposed to the finger like congenital type of diverticulum found

in the ileum. The edges of its mouth are well defined, sometimes being sharp and crescentic, as the diameter of the diverticulum beyond the opening into the bowel immediately begins to increase. The edge may be in continuity with one of the plicae inside the lumen of the intestine. The lining of the pouch is smooth, and there is a complete peritoneal covering. In all the cases there is a close relation either to one of the ducts piercing the duodenal wall or to a blood vessel.

When one holds the opened duodenum up to the light, the thinness of the diverticular wall compared with that of the duodenum is at once evident and it is clear from this simple test alone that there is a gross deficiency of the muscular coat.

Microscopic examination of the wall of the diverticulum confirms this view. If the section is taken from the fundus, practically no muscle tissue is to be seen, except for a thin layer not more than one or two fibers deep, usually to be found and which represents the muscularis mucosae. This layer, as in diverticula of the large bowel may be well defined, being thicker, in fact, than in the intestinal wall. This is due to compensatory hypertrophy owing to the deficiency of the muscularis proper. As the wall is examined toward the mouth of the sac, muscle fibers may become more abundant. If a section is now examined which passes through the edge of the opening into the bowel, so that portion of the wall of both the diverticulum and the bowel be included, it is at once clear what has happened. At the angle formed by the abrupt change of direction of the lumen at the lip of the mouth, the muscular coat of the intestine appears to be unusually thick. Immediately, however, there is a diminution in thickness, shared by both the circular and longitudinal fibers and both layers become equally and progressively attenuated until the muscular coat fades away completely, or is represented by an interrupted thin line of muscle not more than one or two fibers in thickness. Toward the fundus it may be difficult to decide whether or not such fibers belong to the muscularis mucosae.

The mucous membrane itself is thinned, but in uncomplicated cases shows little depar-

ture from normal except in the absence of any Brenner's glands

The microscopic description given does not tally with that of all observers. For example Baldwin states that all his 15 postmortem cases are "true, as they all contained muscle. But he says this consisted of a single layer and therefore probably belonged to the muscularis mucosæ. In his summary of the literature previous to 1911 in 47 cases no microscopic report was made. In 20 other cases muscle was found, and in the 16 remaining it was stated to be absent. Jenkinson mentions an operation case with muscle in the wall but gives no detailed description. Basch in another operation case states

muscular coat thin but intact. Jackson describes a case in which the muscularis mucosæ is hypertrophied with a definite but thin true muscle coat. In Moore's case, the muscularis mucosæ is thickened but there is no true muscle coat. In Rolleston and Fenton's 4 cases no muscle was found at all. Diverticula secondary to ulcer have a complete muscular coat. They are in no sense herniations of the mucous membrane through the muscularis of the intestinal wall and a great deal of the conflicting evidence is due to confusion between the ulcer type and the primary type of diverticulum.

It may be concluded therefore that in primary diverticula of the duodenum the true muscular coat is grossly deficient, sometimes to the extent of complete absence.

AGE INCIDENCE

The average age in 25 of these cases is 51.9 years, the eldest being 73 and the youngest 31. In Cryderman's 45 cases diagnosed by X-ray the average age was 51.7 the youngest being 24. There is thus a close agreement between the two series.

There is a striking difference, however in the average age figure between these two X-ray series, and the postmortem series of Linsmayer, Baldwin and Nagel as can be seen in the tabulation on age incidence. If the average age of the combined postmortem figures be taken as 63 a difference of no less than 11 years exists—and is a striking indictment against the policy of accepting

AGE INCIDENCE

		Cases	Average age	Youngest	Oldest
X-ray	Author	25	51.9	31	73
	Cryderman	45	51.7	24	
Postmortem	Linsmayer	33 (single case)	64	36	81
	Baldwin	1	66	47	82
	Nagel	20	61	28	87

the age incidence of any conditions of this type which is based upon postmortem material alone. In 3 of the author's postmortem cases, the average age is 76.

It is difficult to determine the youngest recorded case of primary diverticulum, for records of the past have been so mixed up with diverticula associated with ulcer (in which the age incidence is younger) that one is forced to ignore them. Cryderman's youngest case of 24 might be accepted with the proviso that it was an X-ray diagnosis, and did not pass the absolute test of visual inspection. Huddy's case of acute perforation of a diverticulum of the second part was in a woman of 27. Pilcher's case, reported in 1894 of an enormous pouch interrupting the transverse portion of the duodenum in a boy of 17 had a wall of inflammatory fibrous tissue. It was in all probability a false diverticulum resulting from perforation of the duodenum. At all events the pathology is not sufficiently clear to warrant its acceptance as a primary duodenal diverticulum.

The point which emerges quite clearly from this discussion is that primary diverticula of the acquired type are unknown before the age of 24 and rare before the age of 30.

SEX INCIDENCE

Of 26 cases, 15 were in women and 11 in men. The average age at discovery of the diverticula is, men 49 years and women 52.6 years. Linsmayer's figures are women 27 men 14 and Cryderman's, women 30, men 14. In Baldwin's summary of 67 specimens found in the literature up to 1911 the sex was stated in 35 cases 21 of which occurred in men, and 14 in women. This series cannot, however be regarded as an accurate repre-

sentation as certainly not all the cases in which the sex is mentioned after excluding all cases in which there is any doubt as to the type of diverticulum described the distribution between the sexes is men 112 women 151

SITUATION

By far the greatest number of primary acquired diverticula occur in the second part of the duodenum in close relation to the entrance of the common bile and pancreatic ducts.

The author has not been able to find a single proved case of primary diverticulum in the first part of the duodenum. This is an observation of the greatest significance for although not ruling out all possibility of their occurring in this situation it denotes at least that they like true congenital diverticula must be of extreme rarity and this fact permits the clinician to regard all diverticula of the first part as secondary diverticula. The vast majority of these are due to the presence of an ulcer.

Diverticula of the third part of the duodenum though far less frequently found than in the second part are by no means uncommon. In the 26 X-ray plates 3 postmortem cases and 1 operation case (the first post mortem specimen is included with the X-ray plates) the distribution is as follows:

First part	0
Second part	22
Third part	9
Horizontal limb	4
Vertical limb and flexure	5
Total	31

1 case with 2 diverticula

DISTRIBUTION

The more complete of the series to be found in the literature are shown in the tabulation on distribution.

If the author's cases are added it will be seen that of the 280 cases in which the position has been noted no less than 204 or 73 per cent are situated in the second part.

These figures however show considerable variations in the relative frequency in the various parts. Whereas Baldwin and Spriggs

DISTRIBUTION

	Year	Author	Total	First part	Second part	Horizontal part	Vertical part
Post mortem	1911	Baldwin	5	0	9	5	1
	1914	Linsmayer	4		4		
	1920	Cave	65	0	49	10	
X-ray	1920	Cole and Roberts	26		3		
	1925	Spriggs and Marner	50	0	30	6	4
	1927	Cryderman	40		30	9	
			220	0	182	67	

and Marner find a steady diminution in frequency from the second part to the flexure. In the author's figures diverticula of the ascending part and the flexure and the horizontal limb are in the proportion 5 to 4. The most marked variation from the mean is in Linsmayer's records for in his 41 cases examined post mortem all of them were in the second part. One is at a loss to account for this for anyone who studies Linsmayer's excellent article cannot fail to be convinced that his observations have been made with care.

MULTIPLE DIVERTICULA

In only 1 personal case was more than one diverticulum found. Two diverticula are not, however uncommon as reference to the literature shows. More than two are rare. In an unusual case described and fully investigated by Odgers no less than five pouches were present. Their distribution is as follows: the first 4 centimeters above the ampulla of Vater the second and third perivaterien, the fourth at the upper border of the transverse part dorsal to the pancreas, the fifth at the junction of transverse and ascending parts.

This specimen has been beautifully dissected and is to be found in the Museum of the Royal College of Surgeons.

In their X-ray survey Spriggs and Marner found two pouches in each of 38 patients. In 12 specimens Keith found two pouches in 3 cases. These were paired on either side of the ampulla. Rolleston and Fenton describe a 'bifid diverticulum—identical, apparently, with Keith's in appearance—having a pouch on either side of the ampulla. These authors suggest that this was originally a single pouch

Fig. Diverticulum of the duodenum associated with ulcer. (From sketch made at operation.)

divided into two compartments as a result of tightening of the common bile duct following *visceroptosis*.

Fleischman describes a case with four diverticula, 1 with three and a third with two and Roth 2 cases with two diverticula in each.

In 20 cases Nagel found 6 with two pouches. All were *perivaterien*. Linsmayer in 41 cases found 7 with two and 1 with three.

The diverticula are all necessarily related to the pancreas lying either behind it or partly buried in its substance. In the 15 cases of Baldwin 8 were posterior 3 lying below it and 4 in its substance.

MORBID ANATOMY IN RELATION TO PATHOGENESIS

Situation in relation to the wall of the bowel. In all cases, without exception the diverticula arise from the concave surface of the bowel and are therefore closely related to the pancreas—a relation which those seeking a congenital theory of origin emphasize very strongly. There is little doubt however that the situation on the concave surface is due to the weak areas in the bowel occasioned by the passage of the common bile and pancreatic ducts and the blood vessels. The greater size of the common bile and pancreatic ducts and the long passage obliquely through the wall lead one to expect a greater frequency of primary diverticula associated with it than with the vessels and indeed it is

so as the figures heretofore given show. The third part of the duodenum, though nearly twice as long as the second portion provides only 27 per cent of the total number of cases. All these cases of the second part lie in the concavity of the duodenum, and at or near the ampulla of Vater. Although one cannot define the exact relation of the diverticula to the ampulla in cases examined by X-ray alone postmortem records show that the greater number are intimately related to it. So common is this relation that French writers have coined the descriptive term "*perivaterien*" for diverticula of the second part of the duodenum.

Anatomy. The common bile duct and pancreatic duct of Wirsung run obliquely through the duodenal wall for one-half to three-fourths of an inch and open into the ampulla of Vater on the left wall of the duodenum, slightly to the posterior aspect. The union of these ducts does not take place until they have almost reached the opening in the duodenal papilla. The exact mode of termination of the ducts is subject to slight variations.

The passage of the ducts through the duodenal wall necessitates a considerable gap in the muscle fibers. The longitudinal coat is most affected for in the angle between the tracks of the pancreatic and bile ducts a well defined circular coat exists, whereas the divarication of the muscle fibers of the longitudinal coat is practically continuous.

The pancreatic duct of Santorini pierces the duodenal wall three-fourths inch above and somewhat anterior to the main duct and terminates in a minute orifice which is often difficult to find even on examination of post mortem specimens.

The weakness occasioned by the separation of longitudinal fibers probably continues for some distance below the entrance of the ducts.

The blood vessels. The duodenum is supplied by the inferior pancreaticoduodenal artery of the superior mesenteric and the superior pancreaticoduodenal of the gastroduodenal branch of the gastric artery. The first part also receives some branches from the pyloric artery.

Figure 9 illustrates the dissection of blood vessels after injection with carmine. For the

sake of clearness, the pancreas has been dissected free from the superior mesenteric vessels and common bile duct. This has necessitated division of the small branches of the pancreaticoduodenal arteries supplying the pancreas but has left the duodenal branches undisturbed.

The inferior pancreaticoduodenal is a short thick trunk at its origin from the superior mesenteric, and almost immediately gives rise to a large branch which passes to the left and follows the concave curvature of the duodenum (under cover of the inferior margin of the pancreas) to the flexure. In the specimen dissected the main artery now divides into two branches from which the bowel is supplied by a double arcade anterior and posterior. The anterior branches are easily visible under the peritoneum covering the anterior wall of the duodenum but the posterior branches run under the lower margin of the pancreas.

As the vessels pass to the right they run to either side of the common bile duct and terminate by anastomosing with similar dorsal and ventral branches of the superior pancreaticoduodenal artery. The dorsal and ventral branches in this case arise independently from the gastroduodenal artery.

This arrangement of the duodenal blood supply does not correspond in detail with that described in standard textbooks of anatomy. Similar findings however are reported by Yule, whose article the author discovered after his own dissections were complete.

There is thus a double arcade of supply to that part of the duodenum from a point above the entrance of the common bile and pancreatic ducts and the point at which the superior mesenteric artery crosses the intestine.

If a cross section of the horizontal portion of the duodenum be examined it is seen that the anterior and posterior series of branches are separated by a considerable interval—five-eighths to three-fourths inch at the points at which they pierce the duodenal wall (Fig. 10).

This relation coincides with the situation of diverticula in the third part. Some of the latter are easily visible and anterior their opening being in the same plane as the ante-

Fig. 2. Pulsion diverticulum of the second part of the duodenum 1½ hours after a barium meal. The barium in the colon is due to a barium enema given 3 days previously.

rior branches. Others are posterior, and hidden the opening corresponding with the posterior branches.

Perivaterien diverticula. Perivaterien diverticula are situated in the concavity of the duodenum immediately above the opening of the common bile duct.

In Keith's article 7 single cases are described in this situation. In the 3 cases in which two diverticula are present the pouches appear one on either side of the common bile duct. The right one is in each case the larger. One cannot fail to appreciate Keith's view that in the cases in which two are present we are seeing merely a further stage in the single cases in the formation of these diverticula.

A few cases are to be found in the literature in which the common bile duct or pancreatic duct or both actually open into a diverticulum. I suspect some at least of these cases as being exaggerations of the condition of wide mouthed opening of the common bile duct. Traction by the common bile duct following inflammation in the biliary tract might cause such an opening to be pulled up into a

Fig. 3. Diverticulum of the second part of the duodenum

Fig. 4. Diverticulum of the second part of the duodenum

diverticulum of considerable size as in the case recorded by Benninghoven and Michael. One case in which the accessory duct of the pancreas opened into a diverticulum is also recorded.

The second most frequent site in the second part of the duodenum appears to be above the ampulla but in the same plane and associated with the opening of the accessory pancreatic duct of Santorini in the minor papilla.

Baldwin's analysis of the cases in the second part in the literature up to 1911 and including his own is as follows:

Convexity of duodenum	Cases
Concavity of duodenum	53
Near pylorus	5
Near minor papilla	9
With accessory duct opening into it	1
Near major papilla	2
At major papilla	24
Wirsung's duct opening into it	3
Both ducts opening into it	4

THE THIRD PART—TRANSVERSE ASCENDING AND FLEXURE

In the author's case of double diverticulum the relation between the mouths of the diverticula and the entry through the intestinal wall of two posterior branches of the superior pancreaticoduodenal artery is clearly shown. This relation is so close that there can be no doubt that the pouches herniated through the gap in the musculature occasioned by the entry of the blood vessels. Grant describes a

similar case in which were present two diverticula of the transverse part in the line of the opening of the common bile duct suggesting that a weakness persisted in the longitudinal muscle fibers after being pierced by the duct for some distance along the concave border of the duodenum. That this may be a factor cannot be disputed. A large vessel was, however associated with both diverticula. It bifurcated at the fundus, one branch going to the posterior and the other to the anterior surface of the diverticulum in each case.

When the diverticulum which commences as a small herniation of the mucosa through a gap in the muscular wall increases in size as a result of intraduodenal pressure its mouth increases in size, and takes up more and more of the diameter of the intestine. Thus in a number of cases the exact point of commencement of the pouch cannot be identified. A protrusion of the mucosa occurs on either side of the midline corresponding with the entry of a vessel. As these increase in size they eventually fuse opening into the bowel by a wide mouth which bestrides the midline (corresponding with the mesenteric attachment in the case of the jejunum).

The case with which diverticula are found at operation will depend largely on whether they start in association with the anterior or posterior branches of the superior pancreaticoduodenal artery. The latter will be completely

Fig 5 Diverticulum of the duodenum

obscured by the overlying pancreas. In the transverse part the mouths of the diverticula open downward and the pouches therefore drain readily. The diverticula probably because of this do not tend to get large. The fact that only 2 cases were shown in the author's series of 26 X ray cases may be accounted for by the same token the barium only remaining in the diverticulum for so short a period of time that it escapes the eye of the examiner.

The terminal portion and flexure. Diverticula of the flexure pass inward to the right and below the lower border of the body of the pancreas. This situation is constant though the exact point in the diameter of the bowel from which they arise has not been determined.

Their semidependent position may account for the large size to which they sometimes develop. Jacquelin and Quénu report a diverticulum removed at operation from a woman of 54 which opened from the bowel near the flexure and passed to the right behind the peritoneum as far as the left border of the duodenum. It measured 8 by 2 centimeters and was easily seen in X ray examination. Lund describes a very similar case in which operation was also done. The diverticulum passed from the region of the flexure behind the first part of the duodenum to reach the posterior aspect of the gall bladder. X rays had shown its presence before operation. One or two diverticula were also found in the beginning of the jejunum.

Fig 6 Diverticula of the third part of the duodenum

Diverticula at the flexure play a prominent rôle clinically owing to their tendency to cause symptoms suggesting obstruction to the passage from the duodenum into the jejunum. Krogus describes a case of acute obstruction due to this cause in a woman of 64.

THE PATHOGENESIS

That diverticula such as have been described in the preceding pages are acquired and not inborn is placed beyond reasonable doubt by the age incidence of their discovery. One cannot on the same ground however dispose of the possibility of a congenital factor being responsible at all events in part for their development. Though I should like to state at once that my own investigations do not lead me to subscribe to the likelihood—or even the necessity for postulating such a factor—one cannot pass by the views of men such as Professor Wilkie who formulated so emphatically a congenital theory of origin some 20 years ago without being conscious of some loss of confidence in the validity of one's own conclusions.

The first source of guidance as to the pathogenesis lies in the structure of the wall of these diverticula. There is uniformity of opinion that the muscular coat is deficient. In all my own cases there was a complete lack of muscle at the fundus of the diverticulum, except

Fig. 7 Diverticulum removed at operation from the second part of the duodenum

for that belonging to the muscularis mucosæ. Failure to state the exact place in the diverticulum from which a section was cut and upon which the opinion was formed as to the nature and quantity of muscle found compels one to rely on one's own limited pathological investigation and the comparatively few cases in the literature in which this is clearly stated.

Two views are possible with regard to the muscular deficiency. Either the muscle is deficient from the commencement or it was normal to begin with and became thin as a result of pressure. This latter event appears to be the explanation of most of those who regard the diverticula as of congenital origin. This sequence of events is however unlikely. Congenital diverticula of the ileum do not behave in this way and indeed there is no reason why abnormal pressure inside the duodenal lumen should of its own accord cause atrophy of the muscle of the diverticular wall any more than that of the duodenum whence the diverticulum opens. Tandler has shown that in the early stages of development of the duodenum the epithelial lining of the gut develops in advance of the mesodermal coats, and Wilkie suggests that the outgrowth of an accessory pancreatic bud in the region of the hepatic and the two pancreatic ones at such a stage might result in a diverticulum with an imperfect mesodermal sheath. But in not one of the author's cases was there any question of direct connection between the pancreas and the diverticulum. The latter was in each case separated by a layer of areolar

Fig. 8 X-ray appearance of diverticulum shown in Figure 7 24 hours after commencement of a barium meal.

tissue from the pancreas and there was no difficulty in dissecting it free.

The lack of evidence is quite clearly in favor of the view that these diverticula are hernial protrusions of the bowel lining beginning at a weak spot in the muscularis. The point is being labored somewhat for it is the key to the pathogenesis and unless one is fully prepared to accept this view what follows is not tenable.

The formation of any type of hernia, depends upon the interworking of two factors (a) an area of diminished resistance in the wall enclosing the cavity from which the hernia arises and (b) pressure inside this cavity.

Areas of diminished resistance are furnished in the duodenum by the piercing of its muscular wall by the bile and pancreatic ducts and by the blood vessels, and the constancy with which diverticula are associated with one or other of these structures is sufficient

Fig. 9. The vascular supply of the duodenum. A dissection made after injecting the arteries with carmine jelly.

proof of the contention. The larger the structure piercing the wall, the more frequent should be the presence of a hernial pouch and the facts of incidence bear this out quite closely.

DUODENAL PRESSURE

The pressure inside the duodenum depends upon (a) the contents and (b) the contraction of the muscular wall.

What is the normal pressure in the duodenum? The musculature is as powerful as that elsewhere in the small intestine; therefore a high pressure during contraction is conceivable. But if the pylorus is patent, the duodenum is open at both ends, and under normal conditions of segmental and peristaltic movements the pressure is not greatly raised.

The duodenal pressure has been examined in 13 healthy patients. A radio opaque tube is swallowed by the subject until it is seen under the X ray screen to be past the pylorus. It is then connected to an ordinary water manometer, and the water levels in the two limbs compared. In all cases there was practically no difference caused in the levels except a rise and fall of from 0.5 to 1 centimeter corresponding with the respiratory excursion of the diaphragm.

Fig. 10. The vascular supply of the duodenum. A diagram to illustrate the relation to the bowel wall of the sites of entry of the blood vessels.

If a reading could be made in this way with the pylorus closed and the duodenum contracting it is probable that greater differences in the pressure reading would result. The rapidity with which the stomach contents pass through the duodenum, as demonstrated by X ray, does not suggest that under normal conditions the duodenal contents exert any appreciable pressure upon the duodenal walls.

That under abnormal conditions at least a high pressure may occur in the duodenum is shown by the case which Figure 11 illustrates.

This remarkable appearance was discovered during the course of a barium meal in a female patient aged 62. It shows the common bile duct, the left and right hepatic ducts and even the smaller intrahepatic canaliculi filled with barium. The commencement of the cystic duct is shown, but not the gall bladder. This appearance was present in the roentgenogram taken immediately on swallowing the meal and remained until the 3 hour picture was taken. At 24 hours, the smaller canaliculi could still be seen, but the larger ducts were empty. At 48 hours the liver was clear.

This case furnishes unquestionable evidence that under abnormal conditions at least the pressure inside the duodenum may

Fig. Duodenal pressure. Entry of barium into the hepatic ducts during a barium meal.

rise to a very considerable height. Further evidence that high duodenal pressure occurs lies in the formation of ulcer diverticula; for there is no question that intraduodenal pressure plays a part in the production of these. As Perry and Shaw have pointed out, the duodenum is the only situation in the alimentary tract in which ulcers are followed by diverticula. These workers think the pylorus is largely responsible for a rise in intraduodenal pressure in opposing by its contraction an obstacle to the reflux when the lower part of the duodenum is contracting. The pressure here is greater than elsewhere in the small intestine where the fluid constituents are distributed over a greater length of bowel. In support of this theory of formation of diverticula immediately *distal* to an obstruction these authors describe a case of diverticula of the jejunum associated with a partial congenital diaphragm situated at the duodenojejunal flexure in a man of 40. The aperture in the diaphragm admitted the fifth finger and there were three diverticula meas-

Fig. 12. The ulcer diverticula of the duodenum.

uring 1 by 1 inch on the mesenteric border of the first foot of the jejunum.

How is this high pressure produced? Not by normal segmental and peristaltic contractions, but by irregular inco-ordinated tonic contractions of the circular and longitudinal coats.

Given therefore weak areas in the bowel wall and the possibility of high pressure being caused inside the lumen of the duodenum by irregular muscular contraction an explanation of the mode of origin of these primary diverticula becomes possible.

The mucous membrane of the duodenum is forced into the interval occasioned by the passage through the duodenal wall either of the ducts or the blood vessels by the circular contractions of the duodenal muscle. In the early stages, the mucous membrane will recover its position but once started there will be a certainty of recurrence and a repetition of the event over a number of months or even years will result in a stretching of the interval between the muscle fibers, and its permanent occupation by a wedge-shaped pouch of mucous membrane. This process is easier to study both in the jejunum and the

colon, where the opportunity for observing the earliest stages arises. There can be no doubt, judging from the pathological anatomy, that this is the way that all primary pulsion diverticula start irrespective of their situation in the alimentary tract.

Once the process of mucous membrane in an intermuscular interval is established, the formation of a typical pouch is inevitable, if the patient lives long enough. The resistance to the pressure inside the duodenum is at a minimum. As the pouch is forming it carries with it muscle fibers from the bowel, the quantity varying in different cases but consisting of a very thin layer, or being entirely absent at the fundus of the diverticulum, which was the first portion to herniate. The subsequent size to which the pouch develops depends upon its age—the very large ones are nearly always found in old people—and its position. For example, those in the transverse portion of the duodenum are usually small because of the absence of any stretching force due to the weight of food contents. Those in the second part of the duodenum are probably limited in size by the support given by the pancreas, but those connected with the flexure may become relatively enormous.

In the two latter situations there is practically always a certain degree of stasis as shown by the barium meal and X ray. The failure to empty synchronously with the duodenum is due at first to the lack of an adequate muscular coat.

The high pressure to which the herniation is due is undoubtedly intermittent, and must be continued over a long period of time. Diverticula do not arise as a result of the presence of an acute obstruction to any part of the bowel.

There is an apparent paradox in this theory of development of pulsion diverticula. Both the degree of pressure and the strength of the duodenal wall depend upon the development of the muscular coat. Therefore duodena in which the muscular layer is best developed would have the most impervious wall. But the difficulty passes when it is realized that the muscular contraction which produces pulsion diverticula is an irregular one, there being areas of relaxation of the muscle coat in

tensified between the sites of tonic contraction.

The question of relaxation is an important one. If one segment of muscle is prone to enter into long periods of overaction, it should tend to hypertrophy, or at least to maintain its power. What changes may take place in a neighboring segment, which is not only relaxed for similar periods of time, but has exerted upon it during its relaxation an abnormal pressure generated by the contracting portion? Does it undergo a "relaxation atrophy"? That such a change is associated with diverticula of the large intestine, which are morphologically identical with those of the small intestine, will be made clear from a study of specimens. The relaxation area in these gives a mirror image picture of the neighboring contraction area. Such a relaxation atrophy, should it occur as I believe it does, would explain the ease of formation and progressive increase in size of the diverticula.

The presence of rugæ in some of these diverticula is not inconsistent with the theory of pulsion, for the causal pressure is an intermittent one, and Grey Turner's case of duodenal diverticulum in a woman of 60 in which the mucous membrane was thrown into folds, is not necessarily contrary evidence.

THE RELATION BETWEEN DIVERTICULA AND VISCEROPTOSIS

In many cases X rays show the presence of varying degrees of visceroptosis in subjects with duodenal diverticula, and it has been suggested that in this condition the vessels and bile ducts cause traction upon the intestinal wall, and tend to pull up the mucous membrane through the muscle coat. There may be some truth in this theory with regard to the formation of diverticula in the jejunum, but it is improbable that the duodenum reacts in this way as its comparative fixity to the posterior abdominal wall protects it from sharing in the visceroptotic process except in the severest cases.

The view that mucosal hernias are more likely to occur in the subjects of visceroptosis because of the 'atonicity' and consequent weakness of the bowel wall found in this condition can be entirely discounted. There is

abundant evidence to show that abdominal ptosis bears no relation to the condition of the muscular wall of the hollow viscera.

A possible predisposing cause of increased pressure in the duodenum occasioned by visceroptosis is constriction of the transverse portion by the superior mesenteric vessels. That this is not of very great importance though possibly a contributory factor in some cases is shown by lack of association between ileus of the duodenum and diverticulosis. This lack of cause and effect between chronic ileus and diverticulosis may appear to be evidence against the pulsion theory. This is not the case however. The facts merely show that diverticula do not arise solely as a result of passive pressure of contents upon the intestinal wall.

ACQUIRED DEGENERATION OF THE MUSCLE COAT

Is a primary local degeneration of the muscular wall a factor in producing a locus minoris resistentie? Inflammation of the muscle coat leading to atrophy has been cited as a cause but there is no histological evidence of this. Further the constant situation in the concavity of the duodenum would not be found if such were the case. Senile atrophy is another hypothesis but one which is readily discounted. Emphatically duodenal diverticulosis is not a disease of old age but of early middle age. It is true that postmortem evidence suggests its greater frequency in the aged but the fallacy of this has already been pointed out. It is true too that generally speaking the older the subject the larger the diverticulum. But this is to be expected. The diverticulum tends always to get larger and the older it is the larger it will become.

THE ULCER DIVERTICULUM

Ulcer diverticula form a distinct group. In contradistinction to primary diverticula the ulcer diverticulum is found more readily at operation or at postmortem than by X ray. At postmortem examination the one thing that may easily be missed is not the diverticulum but the healed ulcer which was responsible for it. All that is to be seen, in most cases is a minute smooth whitened area of mucous membrane adjacent to the diver-

ticulum. The opened duodenum must be examined in a good light, if necessary with a lens. The smallness of the visible ulcer is well shown in the accompanying illustration made from a postmortem specimen. In this the artist has, for the sake of clear definition, purposely accentuated the appearance of the ulcer scar. It will be appreciated therefore, how easily such scars may be missed at post mortem examination.

The only other type of diverticulum which occurs in the first part of the duodenum is the true congenital type and this is so excessively rare that one can safely work on the assumption that if a diverticulum is found in the first part of the duodenum there too will the scar of an ulcer be found.

Morbid anatomy. Both the diverticula and the ulcers may be multiple. In 7 postmortem specimens, the numbers were as follows:

- 1 2 cases with 1 ulcer and 1 diverticulum.
- 2 1 case with 2 ulcers and 1 diverticulum.
- 3 2 cases with 2 ulcers and 2 diverticula.
- 4 1 case with 2 ulcers and 3 diverticula.
- 5 1 case with 2 ulcers and 4 diverticula.

Each diverticulum consists of all four layers of the normal duodenum and the peritoneal coat is free and smooth. The mouth is well defined and bounded by a definite ridge of mucous membrane, and the lining of the pouch is smooth. There is no inflammatory process in its wall and the associated ulcer lies at some distance from its edge, and not in the floor or wall. The following is selected as a typical example.

Specimen 6 (Fig. 12). The pyloric end of the stomach and the duodenum have been divided into halves. The lesser curvatures lie next to one another in the illustration.

One-half to three-quarters of an inch distal to the pylorus are two scars of healed ulcers, occupying the anterior and posterior walls of the duodenum, respectively. Just distal to the ulcers is a prominent fold consisting of the whole thickness of the wall encircling the duodenum. Between this fold and the pylorus, the duodenum is pouched out. The pouch on the lesser curvature is subdivided by a well marked fold, again consisting of the whole thickness of the duodenal wall, into two compartments. The mucous membrane lining the pouches is smooth, and their walls are somewhat thinner than that of the rest of the duodenum, but there has been no interference with the muscle coat.

EDWARDS DIVERTICULA OF THE DUODENUM

Pathogenesis The mode of formation of these diverticula is well illustrated by this specimen. The duodenum has been shortened by contraction of scar tissue of the healed ulcers so that the wall of the duodenum is occupied by the ulcers has been puckered up and ballooned outward by intraduodenal pressure to form diverticula. In this case the maximum contraction has taken place in the direction of the long axis of the bowel.

The diverticula are produced by contraction of scar tissue and not by yielding of a weak area in the wall caused by ulceration. The latter probably never occurs. The dense fibrosis produced by the healing of a peptic ulcer would be the last place for the duodenal wall to give if subjected to pressure. In this view, the author is at variance with those expressed in the literature, in particular by Thorek and F. C. Turner both of whom describe diverticula caused by yielding of an ulcer, and describe cases in which the floor is formed by an ulcer crater. Such cases are to be regarded not as diverticula but as a part of the process of destruction of a large penetrating ulcer. A third type is described in which an ulcer is associated with a pulsion diverticulum of the second part. The part if any played by the ulcer in the formation of a perivateren diverticulum is little understood, and therefore the association of the two is best regarded as accidental.

The amount of shortening of the duodenum caused by the contraction of scar tissue is considerable especially in the specimen described where the unaffected portion of the duodenum is so ballooned out. In this case the shortening by actual measurement is 3.6 centimeters on the greater curvature side.

That pressure plays a part albeit a subsidiary one in the production of these diverticula is shown by the lack of rugae on the floor in nearly all the cases. In no case is there any gross deficiency in thickness shown. The slight difference in the diverticula and in some cases between the diverticula and the duodenal wall is due to attrition following the prolonged effect of intraduodenal pressure. But another explanation is possible. The normal contracting power of the duodenum is impeded by the fixed deformity due to the

ulcer, and there may therefore be a disuse atrophy of the muscular wall in the region of the deformity. It is probable that the persistent spasm of muscle associated with ulcers plays a part by helping to create the deformities, which are subsequently fixed by the scar contraction.

Whatever be the true nature of this minor degree of thinning of the muscle coat, the point which the author wishes to make quite clear is that the diverticula are due primarily to puckering of the duodenum due to scar tissues and the effect of intraduodenal pressure is of secondary importance.

These diverticula differ therefore in situation morphology and pathogenesis from the primary pulsion type met with in the second and third parts of the duodenum.

TRACTION DIVERTICULA

In the series of 31 cases of duodenal diverticula diagnosed by X-ray there are 2 examples of diverticula caused by the contraction of scar tissue adherent to the wall of the duodenum. In one of these the diverticulum is situated near the flexure, and is caused by involvement of the duodenal wall in the healing process of an ulcer of the lesser curve.

The second case occurred in a woman patient of 73 and was confirmed at operation. The gall bladder was thick and fibrotic, and densely adherent to the junction of the first and second parts of the duodenum, the wall of which was pulled out by the adherent gall bladder to form a small pouch.

Perry and Shaw describe a similar case. In a patient with chronic cholecystitis the wall of the duodenum was adherent to the liver, and drawn by adhesions into the form of a narrow pointed cul-de-sac. In a second case of these authors, a gall stone was found in a pouch on the right wall of the duodenum midway between the pylorus and the papilla. The pouch was adherent to a shrunken and fibrosed gall bladder. The case suggests the formation of a traction diverticulum, with later a cholecystoduodenal fistula which allowed the gall stone to enter the pouch the opening healing after this had taken place.

That traction upon the common bile duct might pull up the wall of the duodenum into

abundant evidence to show that abdominal ptosis bears no relation to the condition of the muscular wall of the hollow viscera.

A possible predisposing cause of increased pressure in the duodenum occasioned by visceroptosis is constriction of the transverse portion by the superior mesenteric vessels. That this is not of very great importance though possibly a contributory factor in some cases is shown by lack of association between ileus of the duodenum and diverticulosis. This lack of cause and effect between chronic ileus and diverticulosis may appear to be evidence against the pulsion theory. This is not the case however. The facts merely show that diverticula do not arise solely as a result of passive pressure of contents upon the intestinal wall.

ACQUIRED DEGENERATION OF THE MUSCLE COAT

Is a primary local degeneration of the muscular wall a factor in producing a locus minoris resistentiae? Inflammation of the muscle coat leading to atrophy has been cited as a cause, but there is no histological evidence of this. Further the constant situation in the concavity of the duodenum would not be found if such were the case. Senile atrophy is an other hypothesis, but one which is readily discounted. Emphatically duodenal diverticulosis is not a disease of old age but of early middle age. It is true that postmortem evidence suggests its greater frequency in the aged but the fallacy of this has already been pointed out. It is true too that generally speaking the older the subject the larger the diverticulum. But this is to be expected. The diverticulum tends always to get larger and the older it is the larger it will become.

THE ULCER DIVERTICULUM

Ulcer diverticula form a distinct group. In contradistinction to primary diverticula, the ulcer diverticulum is found more readily at operation or at postmortem than by X ray. At postmortem examination the one thing that may easily be missed is not the diverticulum, but the healed ulcer which was responsible for it. All that is to be seen in most cases, is a minute smooth whitened area of mucous membrane adjacent to the diver-

ticulum. The opened duodenum must be examined in a good light, if necessary with a lens. The smallness of the visible ulcer is well shown in the accompanying illustration made from a postmortem specimen. In this the artist has, for the sake of clear definition, purposely accentuated the appearance of the ulcer scar. It will be appreciated therefore, how easily such scars may be missed at post mortem examination.

The only other type of diverticulum which occurs in the first part of the duodenum is the true congenital type and this is so excessively rare that one can safely work on the assumption that if a diverticulum is found in the first part of the duodenum there too will the scar of an ulcer be found.

Morbid anatomy. Both the diverticula and the ulcers may be multiple. In 7 postmortem specimens, the numbers were as follows:

1. 2 cases with 1 ulcer and 1 diverticulum.
2. 1 case with 2 ulcers and 1 diverticulum.
3. 2 cases with 2 ulcers and 2 diverticula.
4. 1 case with 2 ulcers and 3 diverticula.
5. 1 case with 2 ulcers and 4 diverticula.

Each diverticulum consists of all four layers of the normal duodenum and the peritoneal coat is free and smooth. The mouth is well defined and bounded by a definite ridge of mucous membrane, and the lining of the pouch is smooth. There is no inflammatory process in its wall and the associated ulcer lies at some distance from its edge and not in the floor or wall. The following is selected as a typical example.

Specimen 6 (Fig. 12). The pyloric end of the stomach and the duodenum have been divided into halves. The lesser curvatures lie next to one another in the illustration.

THE MECHANISM BY WHICH THE ACIDITY OF AN ACID MEAL IS REDUCED IN THE STOMACH

FREDERICK C. HILL, M.D., LEO C. HENRICH, AND CHARLES M. WILHELM, M.D.,¹ OMAHA, NEBRASKA

THE acid meal, since its introduction by Boldyreff has been used rather extensively in experimental studies on the stomach and has also been employed by several observers in clinical investigations. It consists of from 100 to 300 cubic centimeters of 0.3 per cent to 0.5 per cent hydrochloric acid and may be administered either by mouth or more commonly by means of a stomach tube. This type of meal is emptied out of the stomach somewhat more slowly than water and the stronger the acid is, the more the emptying time is prolonged.

When an acid meal of this character is introduced into the stomach and withdrawn 15 minutes to one-half hour later it is found that the acid during its sojourn in the stomach has been reduced in strength. This reduction is considered by most observers to be due to neutralization of the acid by (1) mucus secreted by the stomach (2) regurgitated fluid from the duodenum, consisting of bile pancreatic juice and succus entericus. With reference to the first suggested cause of the reduction the gastric mucus we (12) have shown by studies on pouches prepared from the entire pyloric region of the stomach of dogs, and also by unpublished investigations on pouches which we prepared from the entire stomach, that the amount of gastric mucus available is not sufficient in quantity nor alkaline enough to account for any significant amount of the reduction noted. The most important factor concerned in reducing the acidity of an acid meal is thus not intragastric, but extragastric; it is the fluid which comes from the duodenum into the stomach.

That this regurgitation of duodenal contents is a common occurrence both in man and in experimental animals has been noted by various observers for many years. Thus in 1909 Ehmman and Lederer noted considerable regurgitation in the Ewald Boas test meal. Ehrenreich, in 1912 found that trypsin

was present in the gastric contents of more than 50 per cent of 61 patients who were suffering from various gastro-intestinal disorders. Medes and Wright tested the contents of the stomach for 3 constituents of the duodenal fluid—bile, trypsin, and sucrose—and found evidence of duodenal regurgitation in all of 23 patients examined. Trypsin was most commonly found, often in the absence of bile, but bile was rarely present without trypsin. Spencer and his coworkers also found a tryptic enzyme to be present in the fasting or resting stomach in nearly all tests. The amount of bile as estimated by the color of the fluid, varied considerably but when the amount of bile was high the amount of trypsin was also increased.

Using the X-ray and an opaque meal, Bolton and Salmond examined 100 persons and actually saw regurgitation in 6. In the 94 remaining they saw antiperistalsis in the duodenum which they considered should be capable of causing regurgitation. Hicks and Visher in X-ray studies, noted rings of constriction and segmental contractions in the duodenum and believed that these could force the duodenal contents back into the stomach if the pylorus were relaxed. These observers also introduced 150 cubic centimeters of 0.5 per cent hydrochloric acid into the stomach and found evidence of regurgitation in 38 per cent of 56 trials in dogs, and 40 per cent of 10 trials in man. They determined the presence of regurgitation only by the presence of bile as they did not consider that much duodenal content could be present in the stomach without it.

It is evident from a consideration of the above data obtained by various methods and by several different workers, that duodenal regurgitation is a factor which must be accepted. It is true that when one uses an acid meal instead of a non-acid meal of the Ewald type there is more regurgitation. In fact as the strength of the acid is increased there is, as

pointed out by Morse and by Medes and Wright, some increase in the amount of regurgitation. Indeed, this fact is one which gives the acid meal a unique value since it gives one an index as to the capacity of the individual to regurgitate duodenal contents and lower excess acidity in the stomach.

With regard to the mechanism by which the reduction of acidity is accomplished however, there is considerable difference of opinion. The mere fact that the acid has been reduced in strength is not proof that it has been neutralized, since another factor that of dilution must be taken into account. The preponderance of opinion at present is that neutralization brings about most of the reduction. Thus Olch attributes greatest importance to neutralization of the acid by regurgitated pancreatic juice. Elman insists that the amount of duodenal fluid necessary to dilute the acid meal is too great for the duodenum to secrete. He points out that to reduce the acid from 140 to 35 (total acidity) 3 volumes of neutral fluid would be necessary whereas only $\frac{3}{4}$ volume of pancreatic juice would be required. He found that using the "alter cursive" method, little reduction occurred when the pancreatic juice was drained outside the body but when the pancreatic juice was allowed to flow into the duodenum again reduction became normal. Ortner on the other hand, believes that dilution alone could account for the reduction noted.

In order to investigate the relative importance of dilution and neutralization we utilized a method of determining the amount of dilution which was first described by Gorham and which we have already used extensively in studies on gastric acidity. The method consists, essentially in adding to the acid test meal a coloring matter so that when dilution occurs the color will decrease in intensity in direct proportion to the dilution. For this purpose phenolsulphonphthalein serves admirably since it is not absorbed by the stomach, and after it has been alkalinized, changes in its color can easily be read on a colorimeter. Details of the method and procedure used are as follows.

The experiments were performed in all cases on healthy dogs about 24 hours after

the last feeding. A stock solution was prepared which consisted of 1,100 cubic centimeters of approximately tenth normal hydrochloric acid in which 12 milligrams of the sodium salt of phenolsulphonphthalein had been previously dissolved. The stomach was first lavaged with some of this solution in order to remove any fasting contents or mucus and then the test meal, which consisted of 300 cubic centimeters of the acid phenol sulphonphthalein stock solution, was introduced. Samples were withdrawn from the stomach every 15 minutes for one hour or as long as any fluid could be obtained. A portion of each sample and a portion of the original test solution were centrifuged, alkalinized by the addition of 1 cubic centimeter of a saturated solution of sodium hydroxide for each 10 cubic centimeters of the sample, and then centrifuged again. The phenolsulphonphthalein concentration of each sample was then determined by means of a colorimeter, using the alkalinized portion of the original test solution as a standard. In the occasional instances in which mucus interfered with the reading by causing turbidity the mucus was precipitated out by the addition of sodium tungstate and sulphuric acid.

The strength of the acid in the acid meal before its introduction into the stomach, and in the fractions removed from the stomach was determined by chemical analysis since it was found that this method gave a more uniformly accurate result than titration. The acid chloride content of the test solution was determined directly, but in the samples removed from the stomach it was necessary to determine the total and neutral chloride, the acid chloride being the difference between these two figures.

The phenolsulphonphthalein reading indicates the percentage concentration of the original acid test solution which is present in the sample removed from the stomach. Consequently the phenolsulphonphthalein reading multiplied by the chloride concentration of the original acid solution gives the acid chloride concentration which would be present in the sample at that dilution if no neutralization has occurred. The acid chloride content of the sample has actually been determined,

Fig. 3. The isthmus has been removed and the cut ends of the gland sutured. This is rarely possible owing to the woody firmness of the gland.

have seen occur with removal of the thyroid isthmus for constrictive symptoms.

The removal of the thyroid isthmus, as shown in Figure 1 b breaks the connection between the two lobes of the thyroid gland and gives immediate relief from pressure symptoms. When however the prethyroid muscles are sutured together over the face of the gland, the two separated lobes tend either to pull together or to be joined by scar tissue (Fig. 1 a and c) thus re-establishing and intensifying the constrictive effect upon the trachea of the encircling, chronically inflamed thyroid gland. Due to the fact that a good sized segment of the constricting ring of organizing thyroid tissue has been removed and the ends are allowed to re-establish their connection this encircling ring of thyroid tissue has been markedly narrowed and, because of this, effectually causes greater tracheal constriction (Fig. 1 c). As the result of such an operative procedure we have seen the tracheal caliber further narrowed to the size of a millet seed so that the patient could not undertake any activity necessitating increased degree of air intake. I have employed this simple operative step (Fig. 4) to prevent possible reunion of the two cut ends of the thyroid isthmus.

If any patient with thyroiditis complains sufficiently of tracheal constriction and if a roentgenogram shows definite tracheal narrowing we remove the entire thyroid isthmus well out to the points where it enters the lateral thyroid lobes. Care is taken to separate the thyroid isthmus completely from the trachea so that after its removal the trachea is left entirely free from any adherent thyroid tissue. All bleeding over the cut ends of thyroid tissue is controlled and, if possible, the cut ends are sutured over (Fig. 3). In most cases, owing to the rigidity of the infil-

Fig. 4. The procedure herein suggested to prevent union of the two cut ends of the thyroid after removal of the isthmus. Note that all thyroid tissue has been removed from the trachea and that the sternohyoid muscles have been sutured to the trachea well out on its lateral walls so that there is a wide gap between their two bellies.

trated thyroid tissue this cannot be satisfactorily accomplished. Whether or not it can be done is unimportant if suturing of the prethyroid muscles to the lateral walls of the trachea (Fig. 4) is employed.

Fine interrupted catgut stitches can be readily passed through the fascia over the trachea without entering the lumen of that structure, and the median edges of the sternohyoid muscles can be sutured to the trachea thus covering the cut ends of the gland and interposing themselves between the cut ends of thyroid tissue so that the segments of thyroid tissue cannot reunite. Two points should be especially emphasized: (1) a wide segment of isthmus must be resected, and (2) the sternohyoid muscles must be attached to the trachea well down on its lateral walls so that a good sized gap is present between the two cut ends of the thyroid (Fig. 4). If one wishes to unite the two bellies of the prethyroid muscles so that the skin flap does not become adherent to the trachea and bob up and down on swallowing, stitches may be inserted further out in the bellies of the sternohyoid muscle and the muscles brought together after those structures have been so freed from their attachment to the sternomastoid borders that they will really displace toward the midline. This, however is usually unnecessary. The procedure described, by interposing and fixing the muscle fibers between the two cut ends of thyroid tissue establishes a gap, breaks the encircling constriction, and permanently insures against the re-establishment of the tracheal constriction.

THE CURABILITY OF MALIGNANT TUMORS OF THE UPPER JAW AND ANTRUM¹GORDON B. NEW, M.D., F.A.C.S., ROCHESTER, MINNESOTA
Section on Laryngology, Oral and Plastic Surgery, The Mayo ClinicCLYDE M. CABOT, M.D., ROCHESTER, MINNESOTA
Fellow in Otolaryngology and Rhinology, The Mayo Foundation

IN the last two decades there has been marked improvement both in the treatment of malignant tumors of the upper jaw and antrum, and in the end results. Twenty years ago resection of the upper jaw was performed in such cases, some patients died following operation and a small number of patients remained well 5 or more years after operation. In 1920 one of us (New) reported a method of treatment of malignant tumors of the upper jaw and antrum by means of cautery and irradiation bringing out the fact that by this method of treatment operative mortality had been eliminated and the number of recurrences had been greatly reduced. Six years later a second report was made of the end results from treatment of 97 patients with malignant tumors of the upper jaw and antrum by means of surgical diathermy, cautery and radium and the fact was again emphasized that the end results revealed that more patients remained well by this method of treatment than by methods previously used.

REVIEW OF LITERATURE

The literature on this subject recently has been very carefully reviewed in a monograph by Öhngren. He traced the development of electro-surgery and irradiation in the treatment of the condition on the Holmgren service of the Sabbatsberg Clinic at Stockholm. At first, the soldering iron or *ferrum candens* was used, large electric cauteries were then developed and finally electro-surgery. Öhngren reviewed both the foreign and American literature, and his monograph is an outstanding contribution to the subject. He has evolved a clinical classification of his own for determining malignancy of the tumor in which he combines the position of the growth, with regard to whether indications for operation are favorable or unfavorable, its activity determined microscopically, and the presence or absence of metastasis. He divides the skull by means of an imaginary plane passing through the inner canthi and angles of the mandible into an anterior inferior or less dangerous portion and into a posterior superior or more dangerous portion. In turn each of these portions is further divided into

four regions: two lateral and two medial. Tumors in the medial posterior superior regions are much more dangerous and treatment is more likely to result in a smaller percentage of cures than with those in the lateral anterior inferior regions.

In England, the method of treating these tumors also has undergone evolution, as is indicated by two symposiums in the Section of Laryngology of the Royal Society of Medicine in 1922 and in 1931. In the first discussion the consensus was that these tumors should be removed by surgical cutting methods, the operative technique was stressed and the method of using cautery and diathermy was thought little of by practically all the members. In November 1931, however, the discussion revealed that the values of diathermy and of irradiation were appreciated and that resection by means of knife and scissors was little used.

A similar change in the treatment of these tumors has taken place in this country, as is indicated in articles by Sharp by Quick, and by Houser. Most radiologists, however, make an opening into the antrum for purposes of drainage only and they do not attempt to destroy the tumor when that is advisable, with surgical diathermy.

DIAGNOSIS

A diagnosis of *epithelioma of the upper jaw* when the growth originates in the mucous membrane is of course not a difficult one. At times the condition is associated with papillary leukoplakia, a condition which potentially is malignant and should be treated as such. Adenocarcinoma of mixed tumor type usually occurs posteriorly in the upper jaw and palate and as a rule presents a nonulcerated smooth, hard surface. Fresh, frozen sections should be used in all cases to make a diagnosis at the time of operation, in order to determine the type of malignancy and its activity.

Patients with a constant complaint of some pain or uneasiness in the upper jaw or in the face whose symptoms have been of short duration and who state that the pain or uneasiness has been made worse by lying down should be carefully examined to exclude malignant tumor as the cause

Fig. 1 Osteitis deformans of the upper jaw. The right antrum is involved.

of the pain. Roentgenograms should be made and careful study carried out to exclude any involvement of bone. In the indeterminate cases, with symptoms indicating a possible tumor of the antrum, it is advisable to explore the antrum above the alveolar process in order to make sure that the patient's pain is not due to a malignant condition in the antrum. This exploration should

Fig. 3 Fibrosarcoma of the right antrum and upper jaw.

Fig. 2 Giant cell tumor of the right antrum.

be carried out by the surgeon who is equipped to take care of the condition. If it is found to be malignant, thus avoiding the necessity for two separate operations, first, exploration and biopsy and then, later, a second operation in which the malignant condition is cared for. Trauma associated with such a preliminary exploratory operation usually adds to the difficulties in determining the extent of the tumor at the second operation, and it is in these cases that recurrence is most likely to take place (Figs. 1 to 6).

In the differential diagnosis of malignant tumor of the antrum, one must consider giant cell tumor, osteitis deformans, fibroma, adamantinoma, benign cyst, and osteoma. The roentgenogram is a great aid in determining, before operation, the type of tumor and its extent.

CASES STUDIED

We are presenting a study of 295 patients with malignant tumor of the upper jaw and antrum, who were operated on prior to January 1, 1929, in order to determine the curability of these tumors. There were 141 tumors of the antrum, of which 91 apparently were primary and 50 apparently secondary, and 154 tumors of the upper jaw. The division between primary and secondary tumors of the antrum is not absolute, since difficulty arose at times in determining whether the tumor originated in the jaw or in the antrum; the division is important, however, because of the difference in prognosis in the two groups.

Fig. 4. Fibro-osteoma of the left antrum and upper jaw

Of the 91 primary malignant tumors of the antrum, 63 were squamous cell epitheliomata, 6 adenocarcinomata, 7 round cell sarcomata, 9 fibrosarcomata or osteosarcomata, 3 lymphosarcomata, 2 malignant tumors of undetermined cell type, and one was a myxosarcoma. The tumor was situated on the right side in 42 cases and on the left side in 49 cases, 46.2 and 53.8 per cent, respectively.

Of the 50 secondary malignant tumors of the antrum, 30 were squamous cell epitheliomata, 5 adenocarcinomata, 11 malignant tumors of undetermined cell type, 2, fibrosarcomata, 1 was a round cell sarcoma, and 1 a myxosarcoma. The tumor was situated on the right side in 25 cases and on the left side in 25 cases.

Distribution by age and sex. Of the 91 patients in the group with primary malignant tumor of the antrum, 48 were men and 43 were women, an approximately equal distribution between the sexes. The average age of the men in this group was 46 years and of the women 49 years. Of the 50 patients with secondary malignant tumor of the antrum, 44 were men and only 6 women, or 88 per cent compared to 12 per cent. The average age of the men in this group was 53 years and of the women 39 years. Of these 141 patients with primary or secondary malignant tumor of the antrum, 92 were men and 49 women, 65.2 per cent compared to 34.8 per cent. The average age of the men in both these groups was 49 years and of the women 47 years.

Malignant tumors of the upper jaw occurred approximately three times as often among the

Fig. 5. Fibrosarcoma of the left antrum

men in this group as among the women, 74 per cent, compared to 26 per cent. Of the 154 patients in the group, the average age of the men was 54 years and of the women 44 years.

Of the 295 patients in the series, 206 were men and 89 women, 69.8 per cent compared to 30.2 per cent. The average age of men in the series was 52 years and of women, 46 years.

Treatment. The selection of cases for operation is based on the situation and extent of the growth,

Fig. 6. Epithelioma of the left antrum.

TABLE I—SURVIVAL AFTER OPERATION FOR VARIOUS CONDITIONS

Condition	Underwent operation			Lived after operation		
	Free	Patients	Traced	Patients	Percent of traced patients	1 case
Antrum	20	91	75	30	40	5 of 30

			69	30	29	5 of 30

the type of tumor and the presence or absence of metastasis, and in addition the patient's general condition and ability to return for observation. These patients should be followed up carefully after operation so that if the growth recurs they can be treated immediately. Patients with extensive primary antral tumors of highly malignant type have a better chance of recovery than those with tumors of the same size but of a low grade of malignancy so that patients with very extensive, squamous cell epitheliomata, graded 4, or with sarcomata are treated.

The treatment of tumors of this type has been outlined by us in previous reports. In most of our cases anesthesia is by intratracheal administration of nitrous oxide the tumor as a rule being approached through the mouth above the alveolar process or through the palate depending on its situation. Biopsy is made and a fresh frozen section is examined microscopically to determine

the type of growth. In addition, lateral rhinotomy may be employed an incision is made lateral to, and below the nose, a portion of the nasal bone removed and the growth destroyed through this approach. In the treatment of lesions of low grade, the aim is to destroy the tumor completely with diathermy and with the more highly malignant tumors to establish thorough drainage by means of destruction by diathermy. radium is then inserted if it is required. A protected endotherm point with the spark gap almost closed, is used in approaching the more dangerous regions about the orbit or the ethmoid bone, whereas a large point with the spark gap well open, is employed in regions wherein wide destruction will not be of any serious consequence. Preliminary ligation of the external carotid artery is not done as a routine measure but is employed only in an occasional case in which secondary bleeding necessitates its use.

Fig 7 Survival after operation for primary antral malignancy

Postoperative observation every month or 6 weeks is advisable in cases of malignant tumor of the antrum. Sequestra are removed as soon as they tend to loosen. A vulcanite dental plate is used to close the postoperative opening in the upper jaw and is much preferable to a pedicled flap brought in from the neck. It is difficult to get a dental plate with artificial teeth that fits satisfactorily over the flap used to close a large postoperative opening in the jaw. Postoperative perforations in the cheek or nose which occur in a small group of patients, are best closed by tubed flaps brought up from the neck and thorax. In most cases it is necessary to line the flap with a full thickness skin graft in order to obtain a double layer of epithelium and to get a flat graft. We prefer to raise a flap with the upper end in the supraclavicular region and the lower end extending down over the thorax. After delaying it the distal end is carried to the mastoid region and at the next stage, the proximal end in the region of the clavicle which has been lined with a full thickness skin graft, is brought to the area on the face where it is required. This method eliminates the scarring of the neck that follows the use of a tubed flap in the cervical region as usually is employed. The character of the skin in the supraclavicular region is similar to that on the face and makes for a very satisfactory cosmetic result.

Results The results of treatment of malignant tumors of the upper jaw and of the antrum are

given in Table I. There was but 1 death in this series during the postoperative period of convalescence; this patient died of bronchopneumonia during an epidemic of influenza.

The results of Holmgren and Ohngren reveal 38.5 per cent (± 6.7) five year cures in 53 cases of malignant tumor of the antrum. They were able to trace all of their patients, whereas of 141 patients with primary or secondary malignant tumor of the antrum who were operated on prior to January 1, 1929, we were able to trace 118 of these; 53 were well without recurrence, which makes 44.9 per cent 5 year cures among patients who were traced or 37.5 per cent of the number operated on. Houser reported 15 cases, with 13.3 per cent 5 year cures and Peyton reported 11 cases; 2 of Peyton's patients are still living 1 for more than 5 years (Figs. 7 to 10).

Of patients with primary malignant tumor of the antrum 40 per cent of those who were traced were alive without recurrence 5 years after operation. Among patients with primary sarcoma of the antrum 72.2 per cent of those who were traced were alive without recurrence 5 years after operation. The fact that many of the growths were of low grade malignancy accounts for these results. Of patients with primary epithelioma of the antrum who were traced and the tumor graded a higher percentage of those with tumors of low grade (grades 1 and 2) were alive without recurrence 5 years after operation than were those with tumors of high grade (grades 3 and 4) 55.6

Fig 8 Survival after operation for secondary anal malignancy

Fig 9 Survival after operation primary and secondary malignancy of the antrum, taken together

Fig. 10. Survival after operation for malignancy of the antrum and upper jaw

per cent as compared to 34.5 per cent. Of patients with primary adenocarcinoma of the antrum 33.3 per cent of those traced were alive and without recurrence 5 years after operation although these tumors are of low grade of malignancy they are not radiosensitive and complete destruction with diathermy offers the best chance of treatment. Of patients with secondary malignant tumors of the antrum 53.4 per cent of those traced were alive without recurrence 5 years after operation. These tumors originate in the upper jaw and the prognosis is better than with primary malignant tumors of the antrum. Of patients with adenocarcinoma originating in the upper jaw and involving the antrum secondarily 60.2 per cent of those traced were alive and without recurrence 5 years after operation. Of the entire group of patients with primary or secondary malignant tumor of the antrum, 44.9 per cent of those traced were alive and free from recurrence 5 years or more after operation.

Of patients with malignant tumor of the upper jaw including the palate, 62.7 per cent of those

traced were alive and free of recurrence 5 years or more after operation. Of patients with malignant tumor of the upper jaw without involvement of lymph nodes 68.3 per cent of those traced were alive and free from recurrence 5 years or more after operation whereas of those with involvement of lymph nodes only 26.7 per cent of those traced were alive without recurrence 5 years or more after operation.

Of the entire group of 295 patients with malignant tumor of the upper jaw and antrum 236 were traced and of these 127 patients or 52.8 per cent, were alive without recurrence 5 years or more after operation.

CONCLUSIONS

1. Malignant tumors of the upper jaw and of the antrum are curable.
2. Surgical diathermy and irradiation are the most efficient measures of treatment.
3. Biopsy should be made in all cases at the time of operation as an aid in determining treatment.

CONGENITAL ARTERIOVENOUS FISTULÆ OF THE EXTREMITIES VISUALIZED BY ARTERIOGRAPHY

BAVARD T. HORTON, MD, F.A.C.P. AND RALPH K. GHORMLEY, MD, F.A.C.S. ROCHESTER, MINNESOTA

ARTERIOGRAPHY by means of thorotrast is a satisfactory way of visualizing arteriovenous fistula in the extremities, and it permits study of the situation and structure of such lesions before surgical exploration. The importance of the method is illustrated by the following reports, and so far as we are aware, these represent the first cases of congenital arteriovenous fistula to be studied in this manner in both cases surgical treatment was successful.

The surgical treatment of congenital arteriovenous fistula of an extremity hitherto has been extremely unsatisfactory if one can judge from reports in the literature. This is due to the fact that, in the congenital type, abnormal communication between the arteries and veins is usually multiple and for that reason extremely difficult to find at surgical exploration. According to Lewis, only 30 cases of congenital arteriovenous fistula of an extremity were recorded in the literature in 1930. In 19 of these cases, surgical exploration had been carried out in an attempt to close the fistula. This was followed by amputation of the involved extremity in 11 cases; in other words 58 per cent of the extremities found to be involved at exploratory operation were subsequently amputated (this percentage probably would be higher if follow-up information had been

available in all of the cases). Surgical cure was obtained in only one case, and that was the case reported by Lewis of a woman who had an arteriovenous fistula in the region of the right elbow. It is possible that this represented an acquired rather than a congenital arteriovenous fistula, as there was a history of an injury which was followed 2 hours later by pain and by swelling in the right elbow. Then too in this case apparently only a single abnormal arteriovenous communication was found at the time of surgical exploration.

One of us (Horton) reported 23 cases of congenital arteriovenous fistula of the extremities which were observed at the Mayo Clinic from June 28 1929 to May 11 1931. Surgical explorations were not attempted in this series of cases. However one of these patients, a man aged 44 years with a congenital arteriovenous fistula of the left leg was successfully treated following 7 injections of quinine ethyl carbamate. This patient has remained well. In addition to the case reported by Lewis, Rlenhoff in 1924, and Reid, in 1925 reported cases of congenital arteriovenous fistula, involving the vessels of the left and right sides of the neck, respectively, in which the patients were successfully treated surgically.

Every subject with congenital arteriovenous fistula of an extremity should be studied by means of arteriography before surgical exploration is carried out.

Bare reports of the 2 following cases have been given by us before the staff of the Mayo Clinic.

REPORT OF CASES

CASE 1. A man, aged 60 years, came to the clinic December 4, 1933, because of pain and swelling of the right index finger of about 2 years duration. There was no definite history of injury to the finger which could account for his symptoms. April 9, 1933, he had sustained a fracture of the distal end of the right radius, but this had healed in a satisfactory manner without fixation of motion of the wrist joint.

The only significant finding on general physical examination was the condition of the right hand (Fig. 1). The patient was of normal build and weighed 195 pounds (88.5 kilograms). The blood pressure in millimeters of mercury was 170 systolic and 103 diastolic in the right arm, and 170 systolic and 110 diastolic in the left arm. The pulse rate was 70 beats per minute. There was spotty swelling of the index finger with beginning gangrene at the tip. The veins of this finger were definitely enlarged as compared with those of other digits. The maximal surface temperature of the right hand was higher by from 2.5 to

Fig. 1. The patient's hands at the time of admission. The cyanotic appearance of the right index finger can clearly be seen. The left hand was normal. (Case 1.)

Fig. 2. Arteriogram of the right hand (December 6, 1933) after injection of an opaque substance into the brachial artery. a. The arterial tree is well outlined, but the opaque medium has not entered the distal portion of the right

index finger. b. The venous tree is well outlined but that fistula in the index finger are present is evident. av, Showing the region in which the arteriovenous fistula was located (Case 1).

3 degrees C. than that of the left hand. Bradycardiac reaction could not be elicited when the right brachial artery was compressed by means of a sphygmomanometer cuff. A roentgenogram of the right hand revealed erosion of the lateral aspect of the middle phalanx of the index finger. A clinical diagnosis of arteriovenous fistula of the right index finger was made. This was confirmed by the finding of a high admixture of arterial blood in the veins of the right index finger and in those of the right hand. Blood removed under oil from a superficial vein of the right index finger and from one of the right hand, disclosed an oxygen content of 20.15 and 20 per cent by volume, respectively, whereas blood removed in a similar manner from a vein of the left hand disclosed an oxygen content of 15.6 per cent by volume. The oxygen capacity was 21.15 per cent by volume. The oxygen content and capacity of the blood were determined by the Van Slyke gasometric method. The percentage of the saturation of oxygen in the blood was calculated by dividing the oxygen content by the oxygen capacity. The patient had been at rest in a horizontal position for 30 minutes when the specimens of blood were withdrawn. The oxygen saturation of blood from the right index finger was 94.8 per cent and that from the right hand 94.6 per cent. The oxygen saturation of blood from the left hand was 73.8 per cent. An arteriogram following injection of 10 cubic centimeters of thorotrast into the right brachial artery re-

vealed evidence of an abnormal arteriovenous communication in the right index finger (Fig. 2, a and b).

The right index finger was amputated through the meta carpophalangeal joint, and the patient made a satisfactory recovery. The wound healed by primary intention. The

Fig. 3. A dissection of the right index finger illustrating three arteriovenous fistulae. (Case 1).

Fig. 4. Sections taken serially at point *a* in Figure 3. A direct communication between the artery and vein can be seen in the top section (Case 1).

each of the right finger were dissected, and at least 5 arteriovenous fistulae were found between one of the digital arteries and an accompanying vein (Fig. 3). Microscopic sections (Fig. 4) taken serially at a point corresponding to *a* in Figure 3 revealed direct communication between the artery and vein. The vein illustrated in this figure was large and tortuous, and there were many aneurysmal sacs along it. The walls of the veins in most of the microscopic sections were markedly thickened and these veins presented the general appearance of arteries. This was due to the fact that they were functioning as arteries.

Blood removed from veins of the right and left hands, 13 days after amputation of the right index finger, revealed the same concentration of oxygen in the venous blood of each hand. Forty-nine days after amputation of the right index finger, the systolic blood pressure in the right arm was 46 millimeters of mercury and the diastolic pressure, 30. In the left arm, the systolic pressure was 55 and the diastolic pressure 34.

We feel that the diagnosis of congenital arteriovenous fistula of the right index finger has been

established in this case. This is the oldest patient with the condition who has been observed at the clinic. Lesions of this character, when confined to a hand or foot, almost invariably manifest themselves at birth, shortly after birth, or before the age of 20 years.

CASE 2. A man, aged 40 years in 1933, was observed at the clinic in December 1926, February 1928, December, 1929 and again in December 1933. General examination has given essentially negative results at each of this patient's visits to the clinic, except for the condition in the right hand and forearm (Fig. 5). He is a strong, healthy looking individual, and routine laboratory studies have given negative results.

When he first came to the clinic a diagnosis of acquired arteriovenous fistula of the right hand was made, and the case originally was reported as an example of this condition by Carter. We are now of the opinion that this patient's condition was congenital, and one of us (Horton) included this case (as Case 22 in the table) in the report on congenital arteriovenous fistulae published in 1932. The patient thought that his right hand had been injured catching a baseball when he was 20 years of age, and he attributed later developments to this injury. A break in the skin had not been observed at that time. The sudden development of small arteriovenous fistulae in the palm of the right hand at the age of 20 years could hardly account for the overgrowth of bone in the right forearm. The bones of the right forearm were 0.5 centimeters longer than the corresponding bones of the left forearm. Increase in length of a bone occurs apparently only when a fistula has been established for considerable time before ossification of the epiphyseal cartilages takes place. It seems rather evident that this patient had had an abnormal arteriovenous communication in his right hand for a long time, and that his injury had merely aggravated the condition. The right middle finger had been amputated at the metacarpophalangeal joint in 1910, and the wound had healed promptly. On his first admission to the clinic in December 1926, it was observed that the veins in the right forearm and back of the right hand were more prominent than those of the corresponding normal hand. There was a fluctuating, bluish mass, about 2.5 centimeters in diameter at the base of the right fourth finger. This pulsated synchronously with the heart beat. No thrill was present, but a characteristic bruit was heard over the hand, and this bruit was accentuated with each heart beat. Compression of the ulnar artery caused the bruit to disappear; compression of the radial artery produced little effect on the bruit. This pulsating mass was explored by Dr. Pemberton in December 1926, and the third and fourth digital branches of the superficial palmar arch and veins of the stump of the middle finger were ligated. About 8 weeks was required for the wound to heal. The same physical signs were present after the operation as before.

There had been very little change in the appearance of the hand at the time of the patient's second and third admissions, except that the pulsating region in the palm of the hand had increased slightly in size. This increase had been particularly noticeable during the 2 years preceding his last examination. At the last examination, the bruit was more marked than on previous visits, and there was a well developed, palpable thrill in the hand. This was evident when one shook hands with the patient, and the apex beat of the heart decreased from 3 to 5 beats per minute if the hand was gripped firmly. Compression of the ulnar artery did not cause the bruit to disappear.

Blood removed from a large vein of the right forearm

Fig. 5 Appearance of the hands and arms at the time of the patient's admission in December 1933. Marked enlargement of the veins in the right hand and forearm may be noted (Case 2)

Fig. 6 Appearance of the right hand 16 days following amputation of the right fourth finger (amputation of the third finger had been performed at an earlier date) (Case 2)

in 1925 (on the patient's second visit) had an oxygen saturation of 94 per cent. At the patient's last visit, blood removed from a vein at the right elbow had an oxygen content of 90.16 per cent by volume, and blood from a vein at the left elbow 12.49 per cent by volume. The oxygen capacity was 21.17 per cent by volume. The oxygen saturation of the blood in the right arm was 95.3 per cent, and from the left arm 59 per cent. The difference in the color of the blood from the two extremities was sufficient of itself to establish the diagnosis of an arteriovenous fistula, because the blood from the right arm was bright red, indicating its arterial character whereas that from the left arm was dark red, such as one obtains from normal veins.

At the patient's first visit the roentgenogram of the right hand gave evidence of slight periarticular arthritis of the phalangeal joints, and this condition was still present at the last examination.

The maximal surface temperature of the right hand, at the last visit, was 4.7 degrees C. warmer than that of the left. The right hand liberated 101 small calories per minute, whereas the left hand liberated 92 small calories per minute. At the same visit, when the right brachial artery was compressed with a sphygmomanometer cuff the apex beat of the heart decreased from 4 to 6 beats per minute. Blood pressure in the right arm in millimeters of mercury varied from 110 to 140 systolic and from 70 to 78 diastolic. On a previous visit (1928) a systolic blood pressure of 154 millimeters of mercury had been observed in the right arm. In the left arm at the last visit, the systolic blood pressure varied from 105 to 134 and the diastolic blood pressure from 68 to 74.

An arteriogram of the right hand, made in 1933, following injection of 10 cubic centimeters of thorotrast into the right brachial artery revealed an interesting condition (Fig. 7 a and b). None of the opaque material which had been injected into the right brachial artery had entered the fingers. It had been short-circuited by way of the abnormal arteriovenous communications in the hand and had returned to the general circulation by way of the veins. One

of us (Horton) in February 1928, had observed the same phenomenon in this case following injection of 10 cubic centimeters of lipiodol into the right brachial artery.

December 21, 1933, the right fourth finger and a V-shaped portion of the palm of the right hand, including most of the third and fourth metacarpal bones, were removed surgically by one of us (Ghormley). The wound healed by primary intention in 16 days. The circulation in the thumb, index, and fifth fingers returned to normal, and the surface temperature of these digits remained essentially the same as that of the digits of the left hand (Fig. 6). Microscopic sections taken serially through the V-shaped portion of the palm of the right hand revealed many direct communications between the arterioles and venules.

The blood pressure on the first postoperative day was 142 millimeters of mercury systolic and 90 diastolic in the right arm, and 150 systolic and 65 diastolic, in the left arm. On the eighth postoperative day, the blood pressure in the right arm was 135 systolic and 75 diastolic, and in the left arm 100 systolic and 60 diastolic. At this time oxygen determinations of blood from a superficial vein at the right elbow revealed oxygen saturation of 89.9 per cent, and for blood from the corresponding vein of the left elbow oxygen saturation of 83.2 per cent. On the twentieth postoperative day the mean blood pressure in the right arm was 113 systolic and 82 diastolic, and in the left arm 117 systolic and 84 diastolic. Blood removed from a superficial vein at the right elbow on the twenty-second postoperative day was of an oxygen saturation of 81.2 per cent and that from a corresponding vein of the left elbow 77.7 per cent. It is interesting to note that the oxygen saturation of blood from the right arm was slightly higher than that of blood from the left arm following surgical amputation of the right fourth finger and excision of a V-shaped portion of the palm of the right hand. This probably indicates that the patient still had additional, small, abnormal arteriovenous communications in the right upper extremity. Bradycardiac reactions could not be elicited during this latter period of observation.

Fig. 7. Arteriogram of the right hand (December 6, 1933) after injection into the brachial artery of an opaque substance. Arteriovenous fistulae may be seen. The opaque

Since the patient's dismissal, he has written that he is able to use his right hand in plowing and routine farm work. Before the operation his hand was practically useless.

Some interesting clinical observations were made during the period of convalescence. In Case 2, teleoroentgenograms of the heart taken at the time of last admission revealed the transverse diameter to be 14.7 centimeters (Fig. 8a) but 21 days following the operation the transverse diameter of the heart had decreased to 12.6 centimeters (Fig. 8b), an actual decrease of 2.1 centimeters. It was evident that the arteriovenous fistulae in the right hand had been of sufficient size to produce systemic effects on the cardiovascular system. The blood pressure had been slightly higher in the right arm than in the left; the heart rate had been consistently more than 80 beats per

minute and when the right brachial artery was compressed by means of a sphygmomanometer cuff it decreased from 4 to 6 beats per minute. It seems probable that the chief cause of the increase in size of the shadow of the heart was dilation with a minimal amount of hypertrophy although one cannot be entirely sure of this. The decrease in size of the shadow of the heart was chiefly confined to the left ventricle, which is evident when one compares the teleoroentgenograms. This is what one would expect following surgical closure of arteriovenous fistulae such as were present in the right hand of this patient. It is interesting also to note that the total transverse diameter of the shadow of the heart in each instance was less than 50 per cent of the transverse diameter of the thorax.

Fig. 8 a, Teleoroentgenogram of the thorax December 5, 1933, illustrating the size of the heart b, January 11,

1934, showing definite decrease in the size of the heart. The measurements are of the cardiac shadow (Case 2)

Oxygen determinations of the venous blood serve not only to determine whether the patient has an arteriovenous fistula prior to surgical exploration, but also when carried out following surgical operation, to give accurate information as to whether abnormal arteriovenous communications in the extremity have all been closed. This is a simple procedure and a valuable aid in estimating the results of operation. Without oxygen determinations of this character one would have said that a perfect cure had been obtained in Case 2. This, however, is probably not true although from all other clinical standpoints it would appear so.

SUMMARY AND CONCLUSIONS

Arteriography such as was carried out in these 2 cases offers an important means of finding abnormal communications between arteries and veins. One of us (Horton) previously has used this method to demonstrate an acquired arteriovenous fistula in the right thigh following a gunshot wound; this case has been recognized in the literature as the first in which an acquired arteriovenous fistula was visualized by means of arteriography. So far as we are aware the 2 cases herein described are the first cases of congenital arteriovenous fistula in which the condition was

visualized by arteriography. Visualization of arteriovenous fistulae in the extremities of both the congenital and the acquired types can be carried out successfully in most instances and should be of great help to the surgeon in treating such lesions. At present it is only by means of arteriography that the surgeon can learn in which cases operation will be a remedial measure. Therefore it is only by means of arteriography that additional progress will be made in the surgical handling of these vascular anomalies.

RESECTION OF THE KIDNEY¹

HERMAN L. KRITSCHMIR, M.D. I.A.C.S. CHICAGO, ILLINOIS

IN view of the fact that the general tendency in the surgical treatment of various lesions of the kidney has had a distinct trend toward conservatism, and because resection of the kidney is an operation of great possibilities in well selected cases, it does seem strange that the operation has been performed relatively infrequently. In recent publications, both Young and Judd call attention to the fact that the operation is rarely performed.

With the development of modern urology and with the many problems calling for solution particularly from the diagnostic standpoint, it is not surprising that this conservative procedure should temporarily be lost sight of.

Kuester in his monograph published in 1896 collected but 30 cases that had been subjected to a resection of the kidney with a mortality of 16.6 per cent. Perhaps resection fell into temporary disrepute because of the poor results obtained when the operation was first performed. Moreover during the inceptive period of kidney resection the operation was unwisely invoked a matter clearly evidenced by the statistics of Kuester in 16 of the 30 cases, resections were either for tumor or tuberculosis. The lack of refinements of diagnosis in some of the early cases must be held responsible for the failures recorded since the operation was carried out in lesions which we now know are wholly unsuited for resection, among these lesions being malignant tumors and tuberculosis, conditions requiring a radical operation and not a conservative one.

Resections of portions of normally formed kidneys have been done for various pathological conditions and many of them were carried out long before the advent of modern urological diagnosis. Among the various lesions for which resections were done may be mentioned the following:

Spiegelberg (1870) accidentally resected an echinococcus cyst of the right kidney. Wells (1884) accidentally removed about one-third of the left kidney in shelling out a tumor in the region of the kidney. Czerny (1887) resected a tumor an angiosarcoma of the kidney. Keetley (1890) removed by lumbar incision the loose and crushed-off lower extremity of the left kidney after a wagon accident. Waitz (1891) did a resection for pyonephrosis. Bardenheuer (1891) did resections in 2 cases—one for calculus pyonephrosis the other for injury. Kummell (1893) reported 3 cases of resec-

tion—the first a localized inflammatory process (a hard nodule the size of a walnut) the second an abscess caused by a calculus the third an echinococcus disease. Block (1896) resection of a tumor of the kidney an adenoma. Moynihan (1902) reported 3 resections—(1) a solitary cyst (2) a solitary cyst in a connecting band of a horseshoe kidney (3) a tumor. Rathbun in a recent publication reported a series of six resections.

Resections of double kidneys have been performed more frequently than have resections of normally formed kidneys, but this is undoubtedly due to modern urological diagnosis. The lesions are generally infected hydronephroses with or without stone. In this connection it might be well to mention the case of Elsendorath, Philfer and Culver in which the lesion was bilateral and resection on each side was carried out.

In a discussion of resection of the kidney it is necessary to differentiate between two types: (1) resection of a part of a normally formed kidney (2) resection of one-half of a double kidney.

In this series 10 resections were done upon 10 normally formed kidneys as distinguished from double kidneys. The resections were done for the following lesions:

	Cases
Stones	5
Solitary cyst	1
Solitary cyst and stone	1
Traumatic cyst	1
Benign tumor	1
Carbonicle	1

Resection of one-half of a double kidney was done in 6 cases. It has frequently been stated that kidneys which are the seat of congenital anomalies are more prone to undergo pathological changes than are normal kidneys. The 6 resections of double kidneys were done for the following lesions:

	Cases
Hydronephrosis	3
Hydronephrosis and stones	1
Hydronephrosis and ectopic ureter	1
Hydronephrosis and stone in ureter	1

INDICATIONS

1. Whether the solitary kidney is congenital in origin or the result of a previous nephrectomy the problem of treating it when it becomes the seat of a serious lesion is the same. Among the lesions in a solitary kidney that are amenable to resection may be mentioned circumscribed collections of

Fig. 1. Pyelogram after resection in Case 1.

Fig. 2. Pyelogram showing the presence of a large cavity in lower pole of kidney. Stones found in this cavity. Case 2.

TABLE I.—AGES

Age in Years	Cases
Under 10	3
10 to 20	1
20 to 30	3
30 to 40	2
40 to 50	3
50 to 60	3
Over 60	1

Oldest patient, 61 years; youngest patient, 6 years.

stones, especially with infection, the presence of a stone in a calyx with dilatation and with a stricture of the neck, a hydronephrosis with more or less destruction of parenchyma and encysted stones with abscess formation that leads to destruction of the parenchyma. Naturally, when these conditions are present in one of two kidneys resection may just as well be performed.

Resection is also indicated—

2. In cases of bilateral stone in which one pole is diseased or in cases in which there exists a circumscribed stone with pus formation,

3. In cases of partial hydronephrosis of the upper or lower pole with stone formation.

4. In cases of solitary cyst of the kidney. In this group of cases resection is at present recognized as the operation of choice and, as a rule, is very simple and easy of execution.

5. In cases of double kidney with double pelvis in which one-half shows the presence of hydronephrosis, severe infection, or stone.

6. In certain cases of metastatic kidney infection that is carbuncle of the kidney. Resection in a case of this sort proved to be a very wise choice in which the opposite kidney became the seat of a carbuncle. This case (Case 10) had many interesting phases.

7. In case of poor function of opposite kidney.

In Table I is given a summary of the ages of the patients upon whom a resection of the kidney was done.

GROUP I.—NORMALLY FORMED KIDNEYS. RESECTION

Recurrent Right Renal Calculi

CASE 1. D. W. R., male, aged 46 years, was admitted to the Presbyterian Hospital, July 8, 1925. The symptoms be-

gan 22 years ago with left renal colic. The attacks would subside with the passage of gravel. Patient would then remain symptom free for a period of 4 to 5 years when another attack would occur. He also experienced attacks of colic on the right side. Twelve years later, after having received injections of oil in the left ureter, a stone passed. Two years later stones were removed from the right kidney.

For the past 5 years and up to the present admission to the hospital, the patient has complained of a pain in the right kidney region for which he sought relief.

Physical examination was negative. Urinalysis showed no sugar, no albumin, some pus. Examination of blood showed red cells 4,850,000, leucocytes 9,900, hemoglobin 88 per cent. Blood chemistry revealed urea nitrogen, 12.2; uric acid, 2.8; creatinin 1.5; non-protein nitrogen 37.2. The blood pressure was 122/72. The Wassermann reaction was negative. Roentgen-ray examination showed within the right kidney area a large, irregular, dense area, apparently a kidney stone filling the pelvis, and two shadows in the lower pole. Cystoscopic examination revealed a mild cystitis. The bladder was otherwise negative. Both ureters were catheterized without difficulty or obstruction. Examination of the urine obtained at this time showed the following:

	Leucocytes per cu. mm.	Cultures
Bladder	66	Bacillus proteus
Right kidney	1	Bacillus proteus
Left kidney	13	Strep.

Fig. 3 The peculiar shape of the stone in the lower pole of the kidney is shown. At operation a large cavity with a narrow neck was found. Case 3.

By thakem test the output was 74 per cent of the dye for 1 hour.

Operation was done July 1, 1928, under ethylene anesthesia, and consisted of (1) pyelotomy and removal of a large stone from the pelvis, (2) resection of the lower pole of the kidney. In the resected piece of kidney a very large cavity was found that contained two stones.

(The recurrent stones were probably due to the fact that when the stones were previously removed a cavity was left so that the patient again developed kidney stones.)

Result—uneventful recovery.

Subsequent X-ray examinations were negative for stone (Fig. 5).

Left Renal Calculi

CASE 2. H. W. male, aged 30 years, was admitted to the Presbyterian Hospital, June 26, 1920. Attacks of pain in the left kidney region associated with nausea and vomiting began 7 years ago. The pain radiated along the course of the ureter. No hematuria, no frequency of urination, no nocturia were noted. X-ray examination at that time showed a stone in the left ureter which the patient passed 2 weeks later. The patient had no further trouble until 2 weeks ago when he was seized with a pain over the left kidney region which lasted for 24 hours.

Physical examination was negative. Urinalysis showed no sugar, no albumin, some blood, an occasional leucocyte and many red blood cells. Examination of blood showed red cells 4,730,000, leucocytes, 12,000, hemoglobin, 85 per cent. Blood chemistry examinations showed urea nitrogen, 18.3; uric acid, 3.0; creatinin, 1.9; non-protein nitrogen, 30.7. The Wassermann test gave a negative reaction. Roentgen-ray examination revealed a group of shadows in the region of the lower pole of the kidney on the left side. Cystoscopic examination disclosed a normal bladder. Both ureters were catheterized without difficulty or obstruction. Examination of the urine obtained at this time showed:

	Leucocytes per cu. mm.	Cells	Culture	Tubercle bacillus
Bladder	30		Sterile	
Right kidney	20		Sterile	
Left kidney	20	Few granular	Sterile	

Fig. 4 A wedge shaped piece of kidney tissue containing a large cavity and a dumb bell shaped stone as resected. Insert shows the line of suture. Case 3.

Guinea pig tests—Bladder, right and left negative for tuberculosis. The left pyelogram (Fig. 6) showed a rather large pelvis, the calyces clubbed, the inferior calyx broad, not so densely filled as the rest, and with some mottling due to the stone shadows.

Operation was done July 8, 1920, under nitrous oxide and ether anesthesia and consisted of resection of the lower pole of the kidney. This contained a large cavity in which 2 stones were found.

Result—uneventful recovery.

Subsequent roentgen-ray examination showed a complete absence of the nest of calculi previously shown near the lower pole of the kidney. The last (March 16, 1934) examination showed no stone shadows.

Blood chemistry examination, May 10, 1934 showed urea nitrogen, 30; creatinin, 1.71; non-protein nitrogen 32.

Renal Calculi and Ureteral Calculi

CASE 3. Dr. P. P. male, aged 34 years, admitted to the Presbyterian Hospital, November 3, 1927. He has had attacks of bilateral renal colic extending over a period of 15 years, during which time over 30 stones were passed. The attacks were associated with frequency, nocturia, urgency, burning, and intermittent hematuria. Seven years before he came under my observation, stones were removed from the right kidney. Two years later X-ray examination showed a recurrence of stones. The attacks of renal colic and the passage of stones have continued up to the present time.

Physical examination was negative.

Urinalysis showed no albumin, no sugar, no blood, leucocytes 50 per cubic millimeter.

Blood examination revealed red cells, 4,786,000, leucocytes, 14,400, hemoglobin, 90 per cent. The blood pressure was systolic 88, diastolic 78. Roentgen-ray examination showed stones in both kidneys and two low-lying left ureteral stones.

Fig. 5. Resection of the upper third of the kidney. The resected portion of the kidney contained a large cavity with multiple stones. Insert shows the line of closure. Case 4.

Cystoscopic examination of the bladder was negative. The right and left ureters were catheterized without difficulty or obstruction. The urine obtained at this time showed

	Leucocytes per cent	Cultures
Bladder		
Right kidney	4	Sterile
Left kidney	3	Sterile
	90	Sterile

Thalein test revealed a total output of 2 per cent from the right side and 5 per cent from the left side in 30 minutes. Roentgen-ray examination disclosed a large stone in the lower pole of the left kidney and 2 stones in the pelvic portion of the ureter. The stone in the kidney consisted of a very large lower part and an isthmus which was connected with a smaller part of the stone. This stone may be said to have a dumb-bell configuration (Fig. 3).

Over a period of 4 months oil injections were made through a ureteral catheter and during this time one of the stones was passed. The attacks of renal colic recurred more frequently and became more severe. Operation was advised.

On March 16, 1928, under ethylene anesthesia a ureterotomy was done and the stone removed from the left ureter. A second operation was done March 30, 1928, and ethylene anesthesia was again used. At this time the lower pole of the left kidney was resected (Fig. 4).

(It seemed to me that resection of the kidney was clearly indicated because of the large cavity with a narrow neck that would have remained if only the stone had been removed.)

Result: uneventful convalescence.

Multiple Renal Calculi (Right)

CASE 4. C. C. male, aged 13 years, was admitted to the Children's Memorial Hospital, November 9, 1932. At the

Fig. 6. Resection of lower pole of kidney. Insert shows the line of suture. Case 5.

age of 4 months the infant had entered the hospital because of difficulty and pain on urination for which a circumcision was done. When admitted to the hospital, he was suffering from an abdominal pain of the right side, nausea, vomiting and fever. At this time a diagnosis of acute appendicitis was made.

Physical examination revealed a generalized rigidity of moderate degree over the entire abdomen, but especially over the upper right quadrant, tenderness over the entire right side, and a point of severe tenderness 1.5 centimeters above McBurney's point. Urinalysis revealed albumin + acetone ++, benadine ++, 10 to 12 red blood cells per high power field, an occasional leucocyte, numerous cystin crystals, no casts, no bacteria in stained specimen. Blood examination disclosed leucocytes, 19,650, polymorphonuclears, 84 per cent, lymphocytes, 11 per cent. Roentgen-ray examination showed two stone shadows opposite the transverse process of the first lumbar vertebra on the right side. An intravenous pyelogram revealed a slight delay in visualization of the dye on the right side and dilatation of the pelvis and ureter. The kidney and ureter on the left side were normal. There was, however, an increased density of the shadows in the region of the stones in the right kidney.

Operation was done November 23, 1932, and ether anesthesia was used. The upper third of the kidney was resected (Fig. 5) and in it was found a large cavity which contained stones and it had a narrow outlet. Chemical examination of the stones showed pure cystin. Subsequent examinations of the urine during patient's stay in the hospital showed no cystin.

Result: uneventful recovery. Patient was discharged December 12, 1932.

Examination of the urine, April 27, 1933, again showed cystin crystals.

Chemical test for cystin was positive.

Fig. 7. Intravenous pyelogram showing deformity of the pelvis with medial displacement of the ureter and outline of the cyst. Case 6.

Multiple Kidney Stones with Dilatation of the Inferior Calyx

CASE 5. Dr H. R. male aged 39 years, was admitted to the Presbyterian Hospital, June 1, 1932. His first attack of right renal colic began 15 years ago. Subsequent attacks were severe and required morphine for relief. Following the second attack, a stone was passed. A roentgenogram 3 years ago showed three stones in the right kidney. During the past 3 years there has been a fairly constant right lumbar backache. Two or three mild attacks of chills with fever have occurred during the past 2 years and varying amounts of pus and an occasional red blood cell have been found in the urine.

Physical examination disclosed tenderness on deep pressure in the right costovertebral angle. The lower pole of the right kidney was palpable and tender. Bilateral incomplete direct inguinal hernia was noted. Urinalysis showed no albumin, no sugar, no blood, leucocytes occasional, no red blood cells or casts were seen under the microscope. Examination of blood showed red cells, 5,120,000; leucocytes, 8,600; haemoglobin, 90 per cent. The blood pressure was systolic 92 diastolic 50. Roentgen-ray examination disclosed 3 stones in the region of the lower pole of the kidney. Two of the stones were covered by the shadow of the last rib. The thallium test showed total output of dye, 56 per cent for 1 hour.

Operation was done June 3, 1932, and ethylene anaesthetic was used. Resection of the lower pole of the kidney revealed large cavity containing stones (Fig. 6).

Result and careful recovery

Subsequent roentgen-ray examination, January 6, 1933, revealed no signs of calculi at any point. The right kidney outline looked the same as in the picture of a year ago.

Blood chemistry examination, May 6, 1934, showed urea nitrogen, 14; uric acid 5.4; creatinin, 1.4; non-protein nitrogen, 33.

Fig. 8. Large solitary cyst springing from lower pole. Insert A shows the appearance of kidney after resection of cyst; insert B the line of closure. Case 6.

Solitary Cyst

CASE 6. Mrs E. G. aged 45 years, was admitted to the Presbyterian Hospital, June 1, 1933. In June, 1930, a vaginal hysterectomy was done, and the following October patient noticed in the left side of the abdomen at the level of the umbilicus a dull aching pain that radiated through to the back. The pain was intermittent for weeks at a time it was completely absent, and then recurred and remained constant for several days or weeks. After an interval of 2 months, during which the pain was absent, a similar attack occurred, more severe in character. There were no urinary symptoms.

Physical examination was negative except for a cystic swelling of the thyroid and an enlarged left kidney which was smooth, not tender and freely movable. The right kidney was not palpable. Urinalysis revealed no albumin, no blood, no sugar but few red blood cells present in the sediment. Blood examination disclosed red cells, 4,500,000; leucocytes, 11,000; haemoglobin, 84 per cent. Blood chemistry showed urea nitrogen, 11; uric acid, 3; creatinin, 1.4; non-protein nitrogen, 34. The blood pressure was systolic 34, diastolic 76.

Roentgen-ray examination was negative for stone. A large swelling was visible which was attached to the lower pole of the left kidney. The findings were compatible with the finding of a solitary cyst which springs from the lower pole of the kidney.

An intravenous left pyelogram showed the pelvis and calyces pushed up by the tumor mass in the lower pole so that the calyces were compressed in the medial portion and were drawn outward at the upper portion of the upper pole (Fig. 7).

Right Pyelogram—Normal

Cystoscopic Examination—Bladder normal Ureters catheterized without difficulty or obstruction Examination of the urine obtained at this time showed

	Leucocytes per cu mm	Culture
Bladder	0	Sterile
Right kidney	0	Sterile
Left kidney	0	Sterile

Operation was June 9, 1933 and ethylene anesthesia was used. The usual left lumbar incision was made. A large solitary cyst about the size of a grapefruit was found springing from the lower pole of the kidney. The cyst was resected and a nephropexy done (Fig. 8).

Result. Uneventful recovery

Intravenous pyelogram, made July 18, 1933, showed on the left side a slightly distorted pelvis, the right side was normal (Fig. 9).

Solitary Cyst of the Kidney: Stone in the Kidney Pelvis

CASE 7. M. S. G. male, aged 61 years, was admitted to the Presbyterian Hospital, October 21, 1928. His chief complaint was hematuria. About 3 months before entering the hospital, patient had noticed that the urine contained blood. He did not experience pain, however, and he thought that the hematuria was due to a strain. A roentgen-ray examination at that time showed the presence of a stone in the left kidney. The urine cleared up in about a week and no blood had been noticed until a week ago.

Pain over the left kidney had begun about 6 weeks before and was described as a dull sore ache localized over the left kidney region. The pain did not radiate, it was not severe, and bore no relation to urination, respiration, or bowel movements.

Physical examination was negative. Urinalysis revealed no albumin, no sugar, some blood. Microscopic examination of the sediment revealed a few red blood cells. Blood examination showed red cells, 4,460,000; white blood cells, 7,400; hemoglobin, 85 per cent. The blood pressure was systolic 104, diastolic 68. The blood Wassermann test revealed a negative reaction. Blood chemistry examination showed urea nitrogen, 23.5; uric acid, 4.4; creatinin, 2.2; non-protein nitrogen, 49.5. Roentgen-ray examination showed the right kidney outline normal. The left kidney outline was normal except for a globular projection at the lower pole which was visible on several films. There was a dense shadow due to a stone in the region of the inferior calyx. A pyelogram which was made of the left side showed it to be normal.

Cystoscopic examination revealed a small median bar. The bladder was otherwise negative. Both ureters were catheterized without difficulty or obstruction. Examination of the urine obtained at this time showed

	Leucocytes per cu mm	Cultures	Tubercle bacilli
Bladder	10	Sterile	
Right kidney	20	Sterile	0
Left kidney	20	Sterile	0

In the thalium test the total output of the dye, was 20 per cent in 30 minutes on the right side, 17.5 per cent in 30 minutes on the left side. Operation on May 8, 1929 was done under ethylene anesthesia. The stone was removed through a pyelotomy incision and the cyst (lower pole) was resected.

Result. Uneventful recovery

Blood chemistry May 10, 1934, revealed creatinin 1.2; non-protein nitrogen, 36.3.

Fig. 9. Intravenous pyelogram after removal of cyst, showing a slightly distorted pelvis. Case 6.

Traumatic Cyst of Lower Pole of the Right Kidney

CASE 8. L. C. male, aged 54 years, was admitted to the Presbyterian Hospital June 7, 1930. Five months ago, while at work, the patient fell from a height of 6 feet and struck his right side against a roll of paper. He was able to walk, was taken home, and then to a hospital, where he remained for 14 days. He has been unable to work since the injury. Following the fall, blood in the urine was passed and he had pain of a severe nature in the right upper quadrant which was aggravated by movement. The pain was still present, but not so severe as it was immediately after the injury.

Physical examination showed a marked right costovertebral tenderness and slight rigidity of the right rectus muscle. Urinalysis revealed no sugar, no albumin, blood ++. Microscopic examination of the sediment showed many red blood cells and no casts.

Examination of blood showed red cells, 5,300,000; white cells, 8,750; hemoglobin, 82 per cent. Blood chemistry showed urea nitrogen, 30; uric acid, 4.6; creatinin, 1.3; non-protein nitrogen, 45.5. The Wassermann and Kahn tests were negative. The roentgen-ray examination showed no evidence of stone in the urinary tract. Intravenous pyelograms were made and that of the right side showed a filling defect compatible with tumor. The left pyelogram was normal. Cystoscopic examination revealed the bladder and ureteral orifices, normal. Examination showed that the urine from the right and left kidneys and from the bladder was free of pus and sterile upon culture. The findings in the intravenous pyelogram were verified by a retrograde pyelogram.

Pre-operative diagnosis. Because of the presence of a filling defect on the right side, as shown both with an intravenous and a retrograde pyelogram, a diagnosis of tumor—probably hypernephroma—was made and operation was advised.

Operation was done June 18, 1930, and ethylene anesthesia was used. The usual oblique kidney incision was used. Isolation of the kidney was extremely difficult on account of dense adhesions. A cyst the size of a large orange

was found springing from the lower pole of the kidney. The cyst together with a small amount of kidney tissue was resected.

Result: uneventful recovery.

Subsequent course: A right pyelogram was made on April 2, 1931, and this showed a rather small but otherwise normal kidney pelvis.

Adenoma of the Kidney

CASE 9 Miss F. M. aged 24 years. In June 1920, patient noticed an enlargement on the right side of the abdomen but did not consider it of sufficient importance to consult a physician. Three or 4 months later she called the attention of her family physician to the swelling because of its size. No pain or discomfort or any systemic disturbance occurred until within the last few weeks when there were transient, slight aching pains and discomfort on the right side. The mass, according to her statement, progressively increased in size and at no time were large quantities of urine passed.

Physical examination, March 25, 1924, disclosed a large firm tumor mass which occupied almost the entire right half of the abdomen, extending from about 2 inches above the pelvic brim to the costal arch and medially to the midline. The mass was globular in shape, moved with respiration, was not painful upon palpation, and was about 6 inches in diameter. There was present no evidence of fluctuation.

Blood examination revealed red blood cells 4,000,000, leucocytes 6,700, haemoglobin, 95 per cent. The blood pressure was systolic 5, diastolic 75. Urinalysis showed urine cloudy, acid reaction, albumin +, some blood cells, pus + + +, no sugar, no casts, some epithelial cells. Roentgen ray examination showed, in the right kidney region, an area covered by a large soft parts shadow which extended from the twelfth rib to the crest of the ilium and suggested a much enlarged kidney shadow. Cystoscopic examination showed the bladder and ureteral orifices normal. Both ureters were catheterized without difficulty or obstruction. Examination of the urine obtained at this time showed:

	Leucocytes per cu. mm.	Urea	Culture	Cast	Red blood cells
Bladder	30		Sterile		+
Right kidney	90	0.5%	Sterile		++ +
Left kidney	70	0.5%	Sterile		

Time	Right Perc cent	Left Perc cent
at incision and 30 minutes	1	12
Total 45 minutes		20

Right pyelogram showed slight clubbing of the calyces. In the lying position, the pelvis was opposite the first lumbar vertebra; in standing position, the pelvis was opposite the fourth lumbar vertebra.

Diagnosis: tumor of the right kidney.

Operation was done March 28, 1924, under ethylene anaesthesia, and consisted in resection of the tumor and nephrectomy.

Result: uneventful convalescence.

Histological examination revealed an adenoma of the kidney.

Carcinoma of the Kidney

CASE 10 J. R., male, aged eight years, was first admitted to the Presbyterian Hospital, September 17, 1932. At this time a diagnosis of acute pyelitis, due to the *Staphylococcus aureus* was made. The patient was treated with pelvic lavage (1 per cent solution of silver nitrate) and was discharged cured on November 3, 1932. He was admitted to the hospital a second time, February 21, 1933, with chills and fever. There was also noted a mass in the left flank, leucocytosis, and some frequency of urination. A diagnosis of an acute perinephritic abscess was made. The abscess was drained on March 2, 1933, and the patient was discharged on April 15, 1933.

He was admitted to the hospital, a third time, May 31, 1933, because of a persistent sinus in the left flank, tenderness on palpation, and a daily rise of temperature (103 degrees). A retrograde pyelogram (Fig. 6) disclosed a streak of the dye in the region of the left superior calyx. The kidney pelvis and calyces were obscured except for this streak which seemed to be curved upward by a mass which involved the lower 1/3 of the kidney. Urinalysis showed nothing abnormal. The leucocytes numbered 24,700.

Operation was done June 5, 1933, and ethylene and ether anaesthesia was used. The lower half of the left kidney was resected. Result: uneventful convalescence.

Patient was again admitted to the hospital August 16, 1933. Since leaving the hospital about 6 weeks before, he has had no pain, but 10 days ago he began running an afternoon temperature of over 100 degrees, and it was for this reason that he again entered the hospital.

Physical examination revealed extreme tenderness and rigidity to deep palpation on the right side of the abdomen. The impression conveyed was that of the presence of a rounded mass deeply situated in the right upper portion of the abdomen. No tenderness was noted in the left half of the abdomen.

An intra-venous pyelogram showed a progressive filling of the right kidney pelvis and calyces—very little at first, but well filled and dilated on the last film. The pyelogram outline on the right extended through the width of three vertebrae. The left showed small amount of media opposite the first lumbar vertebra and in the ureter. The kidney pelvis and calyces were not outlined and they seemed distorted.

Operation was done September 26, 1933, with ethylene and ether anaesthesia. An incision was made over the right kidney and a perinephal abscess was opened and drained. Patient was discharged from the hospital November 3, 1933.

He was admitted a fifth time November 30, 1933. Eight days after leaving the hospital, a daily elevation in temperature recurring up to 101 degrees, but there was no pain. Physical examination was negative except for the right loin wound which had considerable infected granulation tissue with some purulent discharge. No tenderness was noted in the right flank.

Operation was done November 25, 1933, under ethylene anaesthesia. A large amount of granulation tissue was removed with a curette from the site of the old incision in the right kidney. In the upper end of the wound a large deep cavity was curetted.

Because of the persistent rise in temperature it was deemed advisable to do another operation on the right kidney therefore on January 3, 1934, under ethylene anaesthesia, an incision was made over the draining wound and multiple abscesses in the kidney were incised and drained.

Result: Patient made an uneventful recovery and was discharged, March 2, 1934.

GROUP II—DOUBLE KIDNEYS RESECTION
Complete Reduplication of the Pelvis and Ureter (Left)
Infected Hydronephrosis (Upper Half of Left Kidney)
and Hydro-Ureter

CASE 11. Mrs. A. R. aged 50 years, first entered the Presbyterian Hospital March 2, 1917. Patient gave a history of having had urinary difficulties for 17 years. In 1918 she had had an appendectomy with "no relief" of the symptoms, and within the next 4 years two operations were performed on the bladder for the removal of stones. She was free of symptoms for about 2 years. Upon admission to the hospital, she complained of pain when the bladder was full, pain across the back and left side, frequency of urination, nocturia, urgency and cloudy urine.

Physical examination revealed tenderness over the left upper quadrant and bladder region; otherwise no abnormal symptoms were noted. Urinalysis disclosed no sugar, no albumin, no blood, pus + + + 1 hyaline cast. Examination of blood revealed red cells, 4,800,000; leucocytes, 12,300; haemoglobin, 90 per cent. The blood chemistry examination showed urea nitrogen, 16.86; uric acid, 4.44; creatinin, 1.28; non protein nitrogen, 39.8. The blood pressure was systolic 200, diastolic 120. The Wassermann test gave a negative reaction. The roentgen ray examination was negative for stone. Cystoscopic examination showed a normal bladder with two ureteral orifices on left side; the upper orifices normal. The right ureteral orifice was normal. Both ureters on the left side were catheterized without difficulty or obstruction. The urine at this time showed

	Leucocytes per cent	Culture	Tubercle bacilli
Bladder	5	Staphylococcus epidermidis	
Upper left ureter	536	Staphylococcus epidermidis	
Lower left ureter	20	Sterile	0

In the thalein test (mixed) the total output of dye was 75 per cent in 1 hour. The left pyelogram showed two pelves and two ureters that terminated in the bladder. In the upper pelvis and its corresponding ureter dilatation was marked. The lower pelvis and its ureter was normal (Fig. 11). The right pyelogram was normal. Operation was advised and refused.

On second admission 5 years later patient had the same symptoms and findings except for marked changes in the pyelogram (Fig. 12).

Operation was done March 4, 1933, ethylene anaesthesia being used. A heminephrectomy of the upper half of the double kidney was performed. The ureter to the upper kidney was removed down to the brim of the pelvis, and then nephropexy of the remaining portion of the kidney. At the upper third of the kidney was a line of constriction, above which the kidney showed marked dilatation and was soft and flaccid. There was one blood supply running into the lower half and one into the upper half.

Result: uneventful recovery.

Bilateral Double Kidney and Ureter Hydronephrosis of the Upper Half of the Left Kidney Containing Stones
Stone in the Lower Half of Left Kidney

CASE 12. Dr. J. E. aged 51 years, admitted to the Presbyterian Hospital, October 2, 1933. Symptoms began 18 years ago with an attack of left renal colic, 4 months after which a stone was passed. Nine years later he was seized with an attack of severe renal colic on the left side. Dilatations of the ureter and injections of oil were not successful in securing the passage of the stone, so the ureteral orifice was slit and the stone passed later. Patient was symptom free for 8 years when attacks of renal colic recurred on the right side and were associated with intermittent haematuria and pyuria. About 1 month later (18 months ago) he passed a stone, since which time the urine has continued to show large quantities of pus. Five weeks before entrance to the hospital patient had severe night sweats with chills.

fever of 102 degrees, and hematuria. Ten days ago he experienced a sharp renal colic on the left side which was of short duration and associated with hematuria.

Physical examination was negative. Urinalysis showed no albumin, no sugar, no blood, leucocytes +++.

Examination of blood disclosed red cells, 4,320,000, leucocytes, 6,050, hemoglobin, 95 per cent. Blood chemistry examination revealed creatinin, 1.9 total non-protein nitrogen, 33.3. The blood pressure was systolic 135, diastolic 95.

Cystoscopic examination showed the bladder to be normal. There were two normally placed ureteral openings. Both ureters were catheterized without difficulty or obstruction. The urine obtained at this time showed the following:

	Leucocytes per c.c. urine	Gram reaction	Culture	Tubercle bacilli
Bladder	740	Gram positive cocci	Staphylococcus albus	
Right kidney		No organisms	Sterile	
Left kidney	30	Occasional gram positive cocci	Staphylococcus albus ++	

In the thiamin test the left side showed a total output of 15 per cent of the dye for 1 hour, the right side, 65 per cent for 1 hour. Intravenous pyelograms showed a reduplication of the pelvis and ureter both on the right and left sides. The left upper pelvis showed dilatation and destruction of the calyces; the stone shadows were covered by the media. The lower pelvis showed moderate dilatation (Fig. 5).

Operation was done October 10, 1933, ethylene anesthesia being used. A heminephrectomy was done, resecting the hydronephrotic upper half of the left kidney which contained stones. A pyelotomy of the lower half of the left kidney was done and two stones were removed.

Result: uneventful recovery.

Double Kidney (Right)

CASE 3. Mrs. M. C. aged 41 years was admitted to the Presbyterian Hospital, October 3, 1933. She had had an attack of pain 4 years ago for which she had been given an injection of morphine, and since then has had attacks of pain in the loin occurring at irregular intervals. Associated with this pain, she experienced distress in the bladder and at the external urethral orifice, and had frequency of urination. She also had an attack of hematuria which lasted for one day.

Physical examination was negative except that the lower pole of the right kidney was palpable and tender. Urinalysis showed no sugar, no albumin, no blood, pus + motile bacilli. Examination of blood revealed red cells, 4,000,000, leucocytes, 12,300, hemoglobin, 82 per cent. Blood chemistry showed urea, 50.0, uric acid, 3.0, creatinin, 1.15, non-protein nitrogen, 36. The blood Wassermann test gave a negative reaction. The blood pressure was systolic 120, diastolic 78. The roentgen-ray examination was negative for stone. Cystoscopic examination of the bladder was negative. The right and left ureters were catheterized without difficulty or obstruction. Examination of the urine obtained at this time showed:

	Leucocytes per c.c. urine	Culture
Bladder		Colony bacilli
Right kidney		Sterile
Left kidney		Sterile

Thiamin test returned total output of the dye from the right kidney for 30 minutes, 15 per cent from the left kidney 8 per cent.

The right pyelogram showed reduplication of the kidney pelvis and ureter. The pyelograms on the left showed a normal condition.

Gummi pig test showed the bladder and the right and left kidneys negative for tuberculous.

Operation was advised but refused.

Three years later patient returned, complaining of severe attacks of pain. There was essential change in findings. Operation was advised, and on June 3, 1936, under ethylene anesthesia, patient had a resection of the upper half of the double kidney (hydronephrosis).

Result: uneventful convalescence.

Double Kidney and Double Ureter (Left). Hydronephrosis of Upper Half of Kidney and Hydro-Ureter. Ectopic Ureter.

CASE 14. P. D. female, aged 9 years, was admitted to the Children's Memorial Hospital, September 11, 1930. Urinary dribbling had been present since birth. As a baby, child never had had a dry diaper. It was thought that the child would do better when older and trained, but these expectations were never realized. She urinated frequently and the urine could not be held for long periods of time; between urinations, there was constant dribbling. Condition had become more marked during the past 2 years.

Physical examination was negative except that over the middle of the sacrum in midline dorsally there was a defect in the bone that admitted two fingers. External genitalia were negative except that "just below the external urethral orifice was seen a small opening that discharged urine. A ureteral catheter was inserted into the opening and a prompt flow of urine obtained.

Cystoscopic examination was carried out while the catheter was in place. A normal bladder and its normally located ureteral orifices were found. The ureters were catheterized without difficulty or obstruction. Examination of the urine obtained at this time showed the following:

	Leucocytes per c.c. urine	Culture
Bladder	295	Bacillus proteus aerobius
Accessory ureter	27	Bacillus pyocyaneus
Left ureter	457	Bacillus proteus aerobius
Right ureter	313	Bacillus pyocyaneus

Urinalysis showed albumin ++ blood 0, sugar 0. Sediment showed pus and red blood cells. Examination of blood showed red cells, 4,000,000, white cells, 0,950, hemoglobin, 80 per cent. Roentgen-ray examination was negative for stone but showed spina bifida occulta. A left pyelogram, with shadowgraph catheters in place, showed that the ectopic ureter drained the upper half of the double kidney. There was a marked hydronephrosis in the upper half of the double kidney; the lower half was normal. The right pyelogram showed a moderate hydronephrosis.

Operation was done October 2, 1930, ether anesthesia being used. A heminephrectomy (left) was done with resection of the accessory ureter which was dilated and tortuous.

Result: uneventful recovery.

Fig. 12 Showing marked increase in the dilatation of the ureter and pelvis Case 11

Fig. 13 Dilatation of upper half of double kidney Moderate of lower pelvis Stones covered by skidolane Case 12

Double Kidney, Hydronephrosis Hydro-Ureter of Upper Half Stone in Ureter of Lower Half Retrograde Movement of the Stone

CASE 15 G. H. male, aged 35 years, was admitted to the Presbyterian Hospital December 29, 1931. He had been in good health up to 3 months ago when he first had an attack of severe pain in the right lumbar region which radiated to the right testicle and was associated with gross blood in the urine. The attacks occurred at intervals of 2 to 3 weeks at first, and during the past few weeks almost were daily with 3 to 4 attacks on some days. The pain sometimes occurred only in the testicle. The hematuria was more pronounced during the early attacks than at present.

Physical examination was negative. Urinalysis showed albumin + sugar 0, blood ++ sediment, loaded with pus cells no casts. Cultures showed *Bacillus pyocyaneus*. Examination of blood showed red cells, 4,310,000 leucocytes, 26,400 hemoglobin, 86 per cent. The blood Wassermann and Kahn tests gave negative reactions. The blood pressure was systolic 134, diastolic 60. Roentgen-ray examination showed a stone opposite the third lumbar vertebra on the right side. A subsequent roentgen-ray examination showed that the stone had wandered back up into the kidney and was located in the inferior calyx.

Cystoscopic examination revealed a normal bladder. Two normally situated ureteral orifices were seen. They were catheterized without difficulty or obstruction. Examination of the urine obtained at this time showed

	Leucocytes per cc. min.	Cultures
Bladder	9,600	<i>Bacillus pyocyaneus</i>
Right kidney	80	<i>Bacillus pyocyaneus</i>
Left kidney	40	sterile

Intravenous pyelograms on the right side moderate dilatation of the kidney pelvis and clubbing of the calyces were noted. The stone shadow was opposite the third lum-

bar vertebra. The left side was normal. (The intravenous pyelogram does not show the upper half of the double kidney on the right side. This is due to the fact that the upper half is completely destroyed. There is no secreting tissue present, hence, visualization of the upper half of the double kidney is absent.)

Operation was advised because the ureteral catheterization treatments failed to deliver the stone.

Operation was done March 14, 1932 ethylene and ether anesthesia being used. Two ureters and a double kidney were found. The upper half of the kidney was completely destroyed and the ureter enormously dilated (Fig. 14). Resection of the upper hydronephrotic half was carried out (Fig. 15).

A ureterotomy was done with removal of the stone from the ureter that drained the lower half of the double kidney.

Result: uneventful recovery.

Double Kidney and Double Ureter (Right) Hydronephrosis of Lower Half of Kidney Hydro-Ureter

CASE 16 J. P. female, aged 6 years, was admitted to the Children's Memorial Hospital, November 29, 1933. She had always been in good health up to 3 months ago when she first developed a dull, aching pain in the right kidney region. The pain was practically constant and at times worse at night often causing her to cry and keeping her from sleeping. Occasionally she had fever but there were no urinary symptoms. She has always had enuresis. The pain persisted for 6 weeks before she was taken to a doctor. She had some relief of pain with medication.

Physical examination was negative. Urinalysis showed albumin + blood + sugar 0, pus +, and a few red blood cells. Examination of blood revealed red cells, 4,860,000 leucocytes, 11,300 hemoglobin, 86 per cent. Blood chemistry showed non-protein nitrogen 29. The blood pressure was systolic 120 diastolic 80.

FIG. 14. Resected upper half. Case 3.

Roentgen-ray examination was negative for stone. Right pyelogram (intra-venous) showed a streak of dye running from the last rib to the upper border of the fourth lumbar vertebra. The left pyelogram was normal. Retrograde pyelogram (made elsewhere) showed much looping of the catheter in the right ureter. The ureter dilated and formed a loop opposite the fourth lumbar. Dilatation of the pelvis and calyces was also noted.

This child developed a pharyngitis and bilateral otitis media and a bilateral paracentesis was done. Further work on the kidney was postponed and patient was discharged, January 9, 1934.

On second admission, February 27, 1934, no essential change in condition was noted.

Operation was done March 1, 1934, ether anesthesia being used. A heminephrectomy of the lower half of the double kidney was done. The dilated ureter to the lower kidney was removed about 8 centimeters from the pelvis. A nephropexy of the remaining portion of the kidney was done. There was a line of demarcation between the two portions of the kidney and the lower half was composed of a markedly enlarged hydrocephrotic sac with a shell of renal tissue.

Result: uneventful recovery.

This case is interesting in that the lower half of the kidney showed the pathological condition and

FIG. 15. Note enormous dilatation of upper ureter and pelvis. Case 3.

was resected, which is the exception since it is most frequently the upper and embryonic half that is the seat of disease.

My experience agrees with that of Herbst and Polkey who found that the danger of hemorrhage and fistula is rare in the experimental animal.

The question of hemorrhage was not troublesome in this series of cases, neither at the time of the resection nor subsequently. In the cases of double kidneys it was a relatively simple procedure to isolate the vascular supply to the diseased half and to ligate the vessels before the resection was done. If this procedure is followed the operation is practically bloodless.

In the 10 cases of normally formed kidneys in which resection was done, there was no difficulty in controlling the bleeding with sutures. In none of these cases was the bleeding marked. In 1 case with a very slight oozing a piece of fat was transplanted.

Reference to the possibility of a persistent post-operative urinary fistula has been mentioned by some authors. In this series there were no fistulae. Careful suturing will, in all probability prevent the occurrence of a postoperative fistula. When one of the calyces has been opened great care should be exercised in its closure by careful suture.

The determination of the line of resection is generally quite simple. In the cases of double kidney a line of demarcation between the normal half and the pathological half is readily discernible in most cases, although in a rare case such may be absent or poorly defined.

As a rule in the cases of solitary cyst but little difficulty is experienced in finding a line of cleavage between the cyst and the kidney. Likewise in the one case of benign tumor reported in this paper little difficulty was experienced in finding the line of cleavage and it was easily followed by blunt dissection.

If a stone is present and there is also a cavity no line of cleavage can be demonstrated on the surface of the kidney. In such cases great care was taken to remove these cavities completely.

In the presence of stone two kinds of resections were carried out. In 4 cases the line of incision cut across the kidney from its outer to its inner border. In one case, in which the stone corresponded

more or less to a dumb-bell in its configuration a wedge shaped resection of the kidney was done (Fig 4).

THROMBOPHLEBITIS AND EMBOLISM

WITH SPECIAL REFERENCE TO THE DANGER OF PULMONARY EMBOLISM IN THE INJECTION
TREATMENT OF VARICOSE VEINS

FRANK V. THEIS, M.D. CHICAGO, ILLINOIS

From the Department of Surgery, Rush Medical College of the University of Chicago

PULMONARY embolism is generally feared in any case of thrombophlebitis of the lower extremities. Postoperative, infectious, traumatic or spontaneous thrombophlebitis are too frequently associated with embolism. However, Speed in 1927 reported 30 deaths from pulmonary embolism within a 10 year period at the Presbyterian Hospital of Chicago with the location of the thrombus in the lower extremities in only 7 cases. The location of the thrombus is an important factor. Thrombophlebitis in the arm veins alone very seldom leads to this complication. Similarly, a clinically indistinguishable type of thrombophlebitis produced by the injection of chemical irritants for the obliteration of varicose veins is relatively safe from pulmonary embolism. McPheeters (21, 22) in 1928 after a thorough search of the literature, found only 4 cases of fatal pulmonary embolism in a total of 53,000 cases of varicose veins treated by injection.

In 1931 von Karsten Kettel collected reports of 60,000 treated cases of varicose veins with 10 deaths due to pulmonary embolism. Only 1 of these 10 deaths can be attributed to the present recognized technique. Silverman, in 1931 found reports of 17 deaths besides 1 of his own and 3 non-fatal cases of pulmonary embolism. The almost universal use of chemical irritants for obliteration of varicose veins in itself speaks for the safety of this type of thrombosis.

Doubtless other cases of fatal and non-fatal embolism have occurred and have not been reported. Not only the imminent danger of emboli in other types of thrombophlebitis but the knowledge of unreported cases in obliterating varicose veins has contributed to the hesitancy of the general surgeons in particular in accepting the safety of any case of thrombophlebitis. Since the following case of non fatal embolism occurred, careful routine physical examinations and selection of cases, strict postinjection instructions, and co-operation of the patient have prevented recurrence of the complication. This case is reported and discussed to point out the dangers which are not usually recognized by the less experienced in this type of procedure.

REPORT OF CASE

Mrs. P. aged 40 years, reported to the surgical dispensary April 7, 1930, suffering with large tortuous varicosities of the left thigh and leg. The internal saphenous vein was markedly enlarged and anastomosed. Trendelenburg and Perthes signs were positive. She had had the vein condition for years. She complained of left lower abdominal distress and had lost 15 pounds in weight during the previous month. She attributed this to a recent court experience and worry about her divorce. However she was referred to the department of general medicine for a complete check-up. On April 17 she reported back to the surgical dispensary that she had been examined and nothing was found to interfere with the injection treatment. She was then given one injection of 50 per cent dextrose solution in the left internal saphenous vein at the level of the lower thigh. Two days later the expected moderate inflammatory reaction developed and extended to the femoral ovals and calf. Consequently she went to bed. Being without a home and having no one to take care of her she called the social service department and was promptly admitted to the hospital on April 19, 1930.

At the hospital her leg was elevated and hot packs were applied. On the second day her temperature was 100.4 degrees, pulse 84, and respiration 20. On April 22, her general condition was very good and the pain and swelling along the course of the left internal saphenous vein were markedly improved. On April 24 without any change in her general condition, her temperature went up to 101 degrees. She complained of considerable tenderness and distress in the left lower abdomen. No chest pain or dyspnea were present. April 27 (10 days after injection) she was given magnesium sulphate for constipation. She experienced a sharp chest pain which lasted a few minutes. No cough or dyspnea was present and physical examination of the chest was negative. Her temperature rose to 103.4 degrees. Additional history then proved that she had had a left lower abdominal abscess 18 years ago which required 10 months hospitalization. Further inquiry revealed that she did not have the required general examination. Because of her recent divorce, she was anxious to have her sins treated without delay.

On April 28, a diagnosis of recurrent extraperitoneal abscess was made. On advice of a gynecologist on May 3 a posterior colpotomy was performed. After thorough exploration only a small amount of clear serous fluid was found. Otherwise conditions were normal. The serous discharge was thought to be a transudate from an abdominal abscess. Colpotomy drainage continued to be practically nil but the temperature fluctuated between 100 and 101.4 degrees. The left lower abdominal mass rapidly enlarged until it reached the umbilicus. On May 9 the abscess was opened through a left abdominal incision. A large amount of color odored material was evacuated. There was no question about the abdominal location of the abscess as it was completely walled off by omentum and coils of gut.

The day following operation for draining the abscess, a right internal saphenous thrombophlebitis developed 37 to

days later the woman experienced sharp pains posteriorly on both sides of the chest. The next day (May 13, 1930) consolidation of the left lower chest was detected. Repeated aspirations of the left chest revealed a thin yellow serous fluid. No organisms were present on culture. Her temperature came down to normal but the abdominal discharge continued for months (discharged to convalescence home December 12, 1930).

After being in fairly good health for more than a year she suddenly developed a panophthalmitis. This seemed to be of embolic origin. The eyeball was removed.

This is an unusually complicated case of pulmonary embolism to be definitely attributed to the injection of dextrose in varicose veins alone. In the first place, the patient had lost 12 pounds in weight and complained of severe left abdominal distress for more than a month prior to her first visit. Undoubtedly the confinement of the patient to bed, the debility of the patient due to the rapidly developed large abdominal abscess with a very high septic temperature all contributed to the pulmonary embolism. Even if the patient had not received an injection for her varicose veins postoperative thrombophlebitis and embolism could have developed. In fact, definite evidence of embolism was not detected until after thrombophlebitis developed in the right (opposite) leg subsequent to the second operation for draining the abdominal abscess.

Several factors may contribute to pulmonary embolism consequently every means should be used to avoid their occurrence when thrombophlebitis is likely to develop. The following conditions further the development of pulmonary emboli:

1. Limited damage or destruction of the endothelial lining of a vein leading to thrombus formation provides insufficient attachment of the clot to the vein wall.
2. Inactivity of the patient results in the formation of large coagulation stagnation thrombi instead of the limited solid mixed deposition thrombi.
3. Coagulating solutions for intravenous injections produce unattached coagulation clots.
4. Suppurative infection, either caused by direct contamination from surrounding tissues or hematogenous in origin is followed by disintegration and loosening of the clot.
5. Direct trauma or massage of the thrombotic area may loosen and detach a portion of the thrombus.

The extent of intimal damage leading to thrombus formation is of primary importance when the danger of emboli is considered (Fig. 1). Pathologists are frequently unable to locate the origin of a fatal embolism in the saphenous or femoral

Fig. 1. Photomicrograph of laminated postoperative thrombus of the internal saphenous vein. This specimen was obtained at autopsy following death from postoperative pulmonary embolism. The thrombus, *A*, is attached only at the site of origin on a valve *B*. The rest of the clot is completely free from any other intimal attachment, *C*. Practically the entire intima is intact, *D*.

vein. However Aschoff and Kaufmann believe that intimal damage is always present. This damage may be due to trauma at the operative field such as crushing with forceps or ligature or indirect injury by means of retractors to infection either hematogenous through the vasa vasorum or through direct extension from surrounding tissues or to chemical and toxic agents. With the injection treatment of varicose veins skilfully administered a non-coagulating chemical irritant is held undiluted in contact with the intima for sufficient time to insure extensive annular destruction of the endothelium (32, 33). The more extensively the intima is destroyed the more firmly attached will be the thrombus to the vessel wall.

At operation for the removal of biopsy specimens of injected varicose veins it is apparent that the thrombus is firmly adherent. Forceps and scissors are required to separate the thrombus from the vein or the vein from the surrounding tissues (Fig. 2). I am convinced that the attachment of a deposition thrombus at the site of extensive intima damage prevents its detachment with resulting embolism.

This is contrary to McPheeters' investigation (23) which showed that the reverse flow of blood in varicose veins prevents pulmonary embolism. By means of lipiodol and skiodan injections roent

Fig. 2 Photomicrograph of biopsy specimen of thrombosed internal saphenous vein following injection of chemical irritant for the obliteration of varicose veins. (The entire circumference of the intima has been destroyed and no line of demarcation exists between the remaining portion of the vein wall *B* obliterating thrombus, *A* and perivenous tissue *C*.)

genograms revealed the flow of blood away from the heart. Blood pressure readings and posture tests (Trendelenburg and Perthes) substantiated these findings. With the patient in the upright position the reverse flow of blood in varicose veins would hold true but in the prone position the flow is toward the heart.

Inactivity of the patient subsequent to intimal damage is followed by the formation of a red stagnation clot. Debilitated, bedridden patients are most likely to incur this danger especially in the postoperative period. Red stagnation thrombi are somewhat similar to blood clots *in vitro* loosely held together rapidly disintegrating, and contracting away from the wall of the vein. This type of thrombus may occur as the primary clot, i.e. postoperative, or as a secondary coagulation thrombus superimposed on a pre-existing mixed deposition thrombus. These secondary stagnation clots are particularly dangerous in patients confined to bed following the injection treatment of varicose veins.

With the circulation normally maintained by the continued routine activity of the patient, the gradual formation of a deposition thrombus takes place. This is a firm, mixed, and laminated platelet thrombus with a minimum amount of erythrocytes. To each end, proximally and distally a red

clot extends to the next branch (Fig. 3). Under ordinary circulatory conditions, the deposition thrombus at the site of the damaged intima and the proximal and distal red clots are firmly united in a solid mass. However when thromboses once starts, the rapidity of the circulating blood determines the size and type of the resulting thrombus. With markedly impaired circulation the additional red thrombi may not stop at the adjacent branch but may extend into the larger and smaller veins. When marked myocardial degeneration exists, unusually large thrombi may develop from the site of very limited endothelial damage.

The greatest danger of emboli exists in the presence of coagulation thrombophlebitis (18). These thrombi may occur either as primary coagulation clots or secondary to a mixed clot as heretofore described. In almost all of the reported and unreported deaths from pulmonary embolism in the injection treatment of varicose veins, confinement of the patient to bed preceded the complication. Perivenous tissue necrosis from the injections, bilateral multiple injections at one sitting or severe inflammatory reaction from improper selection of cases, or careless surgical asepsis interfere with the normal activity of the patient. Olson reported one death after injection from pulmonary embolism in a patient 3 days after hospitalization. A patient of von Eiselsberg died after 10 days of hospitalization for excision of an area of necrosis and ligation of the saphenous vein. Faure's patient was confined to bed for 16 days after injection she developed a non-fatal pulmonary embolism the day following her discharge from the hospital. Nohl (12) reported 1 death 3 days after hemorrhoidectomy in a patient who had received injections 6 weeks previously. Both Isaac and de Takats (7) reported cases in which patients who had received injection treatment developed pulmonary embolism after confinement to bed for emergency appendectomy. McPheters and Rice had 2 deaths from pulmonary embolism following hospitalization for excision of postinjection necrosis. It is most important that the routine daily activities of the patient should be encouraged during the course of treatments.

The importance of ambulatory treatment of thrombophlebitis when possible cannot be over emphasized. Homans, of the Massachusetts General Hospital, reported 3 deaths from pulmonary embolism in 162 ligation thrombophlebitis cases confined to bed. De Takats (9) advises ambulatory ligations of the internal saphenous vein and has had no deaths from this cause in more than 200 ligations. Viggiano questions the

advisability of confining patients to bed following any varicose vein operation. Instead of the usual 2 to 3 weeks in bed he believes it might be best to permit the patient to be up and about the same day. Meyer Wildisen advises that intravenous or intramuscular injections in general be given in the arms. There is always more movement in the arms than in the legs in bedridden patients. He reports no emboli since this postoperative regimen has been followed. At the Presbyterian Hospital of Chicago 3 bedridden patients developed thrombophlebitis of the arms. No embolic complications occurred.

In my personal series of more than 14,000 injections (882 patients) each one of which was expected to produce an area of thrombophlebitis, only 1 injection was followed by pulmonary emboli and this patient had been confined to bed for 10 days before the complication occurred. Linser, McPheeters (22) and de Takats (8) all advise ambulatory treatment when possible even in the presence of a severe postinjection reaction. However, McPheeters' recommendation that an entire limb be injected at one sitting is entirely too severe to expect the full ambulatory co-operation of the patient. In every case of spontaneous, traumatic, non-suppurative infectious thrombophlebitis in which the patient is already ambulatory, I insist upon continued activity. Even in the presence of a low grade temperature I no longer confine him to bed. In more than 50 such cases I have had no instances of pulmonary embolism or serious complications.

Suppurative infection is extremely serious in the presence of thrombophlebitis. The pyogenic infection might be the cause of the original thrombosis as may occur from a surrounding abscess, from direct inoculation by the injection, or from a septicæmic or pyæmic hematogenous dissemination. Disintegration of the accumulated leucocytes produces proteolytic action of the thrombus itself as well as of the attachment of the thrombus to the wall of the vein. Pyæmia and embolism are very commonly observed. This must not be confused with the non-suppurative inflammatory reaction which is often seen. In a series of these cases Brown was unable to get culture growths from either the inflamed vessel or the contained thrombus.

Coagulating chemicals should never be used in intravenous injections. Early in the injection treatment of varicose veins, Pregl's isotonic iodine solution was advocated. Numerous deaths followed the clotting effect of the solution on the blood. With limited attachment of the thrombus on the wall of the vein the extensive coagulation

Fig. 3. Schematic illustrations showing the formation of an obliterating thrombus in a blood vessel. With an active circulation the occluding thrombus extends from the site of origin on the damaged intima to the next proximal and distal branches. With an inactive stagnant circulation the thrombus may extend for considerable distance to the larger proximal branches. These latter secondary coagulation thrombi are unattached to the wall of the vein (Fig. 1) and are easily dislodged and broken off to form emboli.

thrombus is easily dislodged. Three of the 10 deaths from pulmonary emboli reported by von Karsten Kettel were due to the use of this solution. Its use has been completely discarded (14).

Direct trauma and massage to a thrombotic area are dangerous. The superficial inflammatory reaction which so frequently accompanies thrombophlebitis is occasionally massaged with a liniment or ointment. Even the more intelligent lay people are often inclined to do this unless definitely informed to the contrary. Direct trauma as in athletics may be the cause of breaking loose of a fragment of the thrombus. Kilbourne reported 1 death following massage of the limb after injection.

PREVENTION OF PULMONARY EMBOLISM AFTER INJECTION

Basically thrombophlebitis is always a potential source of embolism. The ruthlessness with which emboli strike and the helplessness of treatment compels the use of preventive measures to avoid thrombosis which cause the emboli. Naturally to produce a thrombophlebitis deliberately could be severely criticized. At the Presbyterian Hospital of Chicago 70 patients were treated dur-

thrombophlebitis

†Death occurred on day following resection of the thrombotic internal saphenous vein

ing the past 10 years for thrombophlebitis of the lower extremities. Twelve or 17.1 per cent developed pulmonary emboli which resulted in 5 deaths—a mortality of 7.1 per cent in patients with thrombophlebitis.

In a series of thirty deaths from postoperative embolism at the Presbyterian Hospital of Chicago, Speed in 1927 found that the thrombosis occurred only 6 times in the leg and once in the thigh. This indicates that thrombosis in the extremities is less apt to cause embolic death than in other locations. However, Cleland and Barlow report that 2.5 per cent of all autopsies showed pulmonary embolism, and in every instance the original clots were found in the leg veins.

Hunt at the City Hospital of Worcester, Massachusetts, reports 94 surgical, traumatic, and obstetrical cases of thrombophlebitis. Almost 25 per cent of these cases with thrombotic complications died of pulmonary embolism. Tempely from the Kuettnier clinic compiled the frequency of thrombosis and embolism according to the seriousness of the surgical condition and the debility of the patient following operation. In carcinoma of the stomach and rectum, pulmonary emboli occurred in 1 to 3 to 1 to 2 cases of thrombosis, respectively. Simple herniotomy was followed by thrombophlebitis in only 0.8 per cent of the cases, but 25 per cent of these developed fatal pulmonary embolism. In appendectomy one embolism occurred to each 7 of thrombophlebitis. Brown, at the Mayo Clinic, recognized pulmonary infarction in 33 per cent of 87 cases of thrombophlebitis although no deaths from pulmonary embolism occurred.

Frequent suggestions appear in the literature attempting to reduce the incidence of thrombophlebitis with its accompanying danger of embolism. In a statistical review of pulmonary em-

bolism Henderson emphasized the importance of age, weight, general condition of the patient, efficiency of circulation, bodily inactivity, and infection. Snell found that obesity or weight did not definitely contribute to embolism. Walters, in a symposium on fatal pulmonary embolism before the 1927 Clinical Congress of the American College of Surgeons, expressed the opinion that lowering of the blood pressure, depression of metabolism, and possibly slowing of the circulation as a result of prolonged rest in bed, play an important part in either the predisposition to, or the causation of, postoperative thrombosis and emboli. Following a regimen to overcome these factors including thyroid medication he reports a 75 per cent reduction in fatal pulmonary embolism. Bancroft and Brown believe that changes in the blood itself are probably the most important. On the other hand Allen, after extensive investigation, states that the "non-specific physiological changes in the blood in all probability play only a minor part in contributing to thrombophlebitis and embolism. Miller believes that the outstanding single factor concerned with thrombophlebitis and embolism is stasis of the blood in the pelvis." In spite of the investigations and reports with suggestions to reduce the incidence of thrombosis and embolism, many European clinics have found an alarming increase.

In discussing the prevention of postoperative pulmonary embolism David advises that "patients should not be allowed to remain in one position during the first few days when so little inclination exists to move. The position of the legs should be frequently changed and in almost all abdominal surgery the patient should be turned on the side for certain periods during the day. It is interesting that in the herein reported 39 cases of postoperative thrombophlebitis of the ex-

tremities at the Presbyterian Hospital of Chicago none occurred on his service. This regimen is particularly valuable in those patients who after injection require confinement to bed for emergency conditions such as appendicitis, etc.

With each injection of a chemical irritant a deposition mixed thrombus adherent to the damaged vein wall is expected to obliterate the varicose vein permanently. In more than 14,000 injections (882 patients) which I have personally given, an equivalent number of potential sources of emboli is provided. However with only 1 injection did this complication occur. In this series the patients' ages ranged from 16 years to 89 years with the large majority between 30 and 45 years. At least 8 per cent were obese, 1 per cent cardiac and $\frac{1}{2}$ per cent controlled diabetics. Another 10 per cent were unusually thin. In 10 per cent of the cases there had been a previous thrombophlebitis. The size of the veins treated varied from the small superficial telangiectatic type to the huge tortuous type covering both leg and thigh. No patient has been refused injection treatment because of age, weight, cardiac compensation, controlled diabetes, or a thrombophlebitis not less than 2 to 5 years previous. However, in less than 4 per cent of the patients injections were postponed because of recent thrombophlebitis, untreated cardiac condition, diabetes, hyperthyroid or other systemic infirmities, serious peripheral arterial disease with danger of impending gangrene, local infection, ulcerations, eczema, indurations or swelling of the legs and feet or systemic infections, such as grippe, colds, bronchitis, etc. I have had called to my attention 3 unreported cases of sudden death following the injection treatment. All had been confined to bed but details are lacking as to the terminal clinical picture.

CONCLUSIONS

Pulmonary embolism may occur in any case of thrombophlebitis. In more than 14,000 injections (882 patients) for the obliteration of varicose veins each one of which was given to produce an area of thrombophlebitis, only 1 was followed by pulmonary embolism and that non-fatal. This did not occur until after 10 days' confinement to bed.

Pulmonary embolism occurs most frequently in bedridden, debilitated and cardiac patients. With limited attachment of the thrombus to the vessel wall the deficient circulation of blood aids extensive secondary red stagnation thrombus formation. These are easily dislodged and carried away in the circulation.

Although thrombophlebitis produced by injection of chemical irritants, trauma, or infection is

indistinguishable clinically nevertheless pathologically there may be a marked difference. The possibility of detachment of a thrombus and embolism formation depends upon the pathological type of thrombus present.

Coagulation or secondary stagnation thrombi because of lack of intimal attachment are particularly prone to cause embolism. The intravenous injection of a coagulating chemical irritant or a very limited break in the intima may be the source of extensive coagulation thrombosis.

Deposition or pulsion (Aschoff) thrombi are expected to obliterate varicose veins following the injection of non-coagulating chemical irritants. Extensive intimal damage provides adequate attachment for the thrombus. There is very little danger of detachment or extensive secondary thrombus formation unless the patient is subsequently bedridden.

Suppurative infection or direct injury to a thrombotic area may contribute to the disintegration or dislodgement of any type of thrombus.

Nevertheless thrombophlebitis of the extremities irrespective of the cause, is less likely to be followed by pulmonary embolism than thrombosis in other locations.

In the injection treatment of varicose veins proper selection of cases for injection, skilled technique and complete cooperation of the patient after injection in continuing routine daily activities will lessen the frequency of pulmonary embolism.

EVOLUTION AND PRESENT TECHNIQUE OF GASTROJEJUNOSTOMY

R. W. McNEALY, M.D., F.A.C.S. AND MANUEL E. LICHTENSTEIN, M.D., F.A.C.S. CHICAGO, ILLINOIS
From the Department of Surgery, Northwestern University Medical School and Cook County Hospital

GASTROJEJUNOSTOMY as it is performed today represents the crystallization of 53 years of scientific observation and development. While part of the knowledge of this branch of gastric surgery is the result of laboratory experimentation, probably more has been acquired by the method of trial and error in clinical surgery. The sustained interest in this operation is perhaps occasioned by the indubitable fact that for those conditions in which it is indicated, it is one of the most satisfactory therapeutic procedures known to surgery.

The first 20 years of experience with this operation occurred contemporaneously with the development of abdominal surgery and the establishment of the principles of physiology of the gastro-intestinal tract. These 20 years may be described as the period of groping in the dark toward a light which probably even now has not attained its full brilliance. The success of the first gastrojejunostomy suggested that it was an operative procedure of value. Difficulties were encountered early and these were not overcome easily because of the incomplete knowledge of the anatomy and physiology of the gastro-intestinal tract. Some 50 different methods, techniques and procedures for the operation have been devised. Many of them have been discarded as valueless yet each has made its contribution to the present day method of gastro-intestinal anastomosis. Good results often followed operations which were not technically sound. The words of Kocher (26) in reply to a criticism of his method are worth repeating.

It is well that Nature is not so ungracious as the surgeon. She allows, just as God allows the sun to shine on good and evil, methods which theoretically are good and bad to be successful.

The first gastrojejunostomy was performed by Anton Woelfler (85) in Billroth's clinic in Vienna on September 28, 1881. Events which led to the performance of this particular operation are of interest. As early as 1874 Gussenbauer and von Winwarther had performed pylorotomy on dogs successfully. Pean did the first partial gastrectomy in 1879 but his patient died. The first successful partial gastrectomy in man was done by Billroth (3) on February 4, 1881. Woelfler, his assistant, reported 3 additional partial gastric resections later in the same year. With the intention of performing a partial gastric resection on an

other case Woelfler opened the abdomen of the patient and found a mass which had infiltrated the surrounding tissues. The infiltration was of such character that gastric resection was impossible. It has been related that he was ready to close the abdomen when Nicoladoni who was present in the clinic at the time, suggested that an anastomosis be made between the stomach and the small intestine. There is no record that even suggests the source of Nicoladoni's inspiration unless it be his acquaintance with the successful performance of entero-anastomosis by Gely and Maisonneuve (36) which was reported in 1864. Woelfler proceeded with the proposal of his colleague and recorded his operative technique as follows:

The stomach was opened one finger's breadth above the attachment of the gastrosplenic ligament at the greater curvature by means of a longitudinal incision 5 centimeters long. A loop of the small intestine was pulled up and split in the same length at the surface situated opposite to the mesentery. The edges of the lumen of the small intestine were then inserted into the edges of the gastric lumen in such a manner that the posterior margins of the intestinal lumen were united with the posterior margins of the lumen of the stomach by internal circular sutures with silk threads. At the anterior margins of the gastric lumen and of the intestinal lumen the margins of the mucous membrane were at first attached to each other, then the serosa and muscularis surfaces by means of a modified Lambert's suture. After careful disinfection of the entire field of operation with carbolic acid, the abdominal layers were again closed, and the united wound was covered with an iodoform dressing. During the entire operation the stomach and the intestinal loop which had to be inserted were placed upon disinfected sponges. In order that during the operation no intestinal contents should escape, the intestine was closed off in the efferent and afferent portion with a thick silk thread which passed through the mesentery. This method of temporary closure appears to be the most simple and the most appropriate. The operation was carried out under strictly antiseptic precautions but without the use of a spray. No drainage of the peritoneal cavity was done. The course following the operation was satisfactory in every way. The patient remained completely free from fever and felt progressively better since the day of operation. The annoying vomiting ceased. From day to day the patient could take progressively larger quantities of food. At first only a liquid diet was given. From the eighth day on solid food was given without undue results. The wound of the abdomen healed under a dressing by first intention. Four weeks after the operation, the patient has daily evacuations of stools, which are firm and brown color. By means of the gastroenterostomy the author has excluded the carabomatous pylorus from the channel of nutrition for which he has found a new way. The food reaching the stomach travels a new way and the inflow of bile and of the pancreatic juice through the afferent portion of the intestinal loop is not prevented. The many physiological questions which are concerned can-

not at present be answered. This much is assured, namely, that all the theoretical considerations which could be cited against the operation are removed by the successful result of the operation.

The final comment of this report is significant.

The success of the operation is established regardless of any theoretical considerations which may be cited against it.

Practically it is of little importance, even today, whether the good results of the operation are due to the neutralizing action of the intestinal juices on the gastric contents, or to simple drainage facilitated by the new outlet of the stomach.

The fortunate outcome of the first case served as a stimulus to its further use. On October 2 1881 4 days after Woelfler's first case, Billroth performed the second gastrotomy (4). His patient also had an irreducible carcinoma of the pylorus which had extended into the pancreas. The operation was terminated within an hour. On the day following the operation, a biliary vomiting developed which persisted until the patient's death on the tenth day. Autopsy showed perfect healing at the site of anastomosis and no peritonitis. The afferent loop of the small intestine measured 11 centimeters. The persistent vomiting was due to a mechanical defect at the site of the anastomosis. A spur formation was produced. The intestine was divided into a larger afferent loop which contained the pancreatic and biliary secretions and a much smaller efferent loop. The lumen of the latter was hidden under the overhanging margin of the gastric stomach. This case pointed out a very important technical error. The afferent loop evacuated its contents into the stomach while the lumen of the efferent loop was so placed that it could not drain the gastric contents. Vomiting was, therefore, the only means of emptying the stomach of the continuous reflux from the afferent loop. Thus attention was called to the fact that suturing of the viscera could be successfully accomplished but some of the mechanical features of the operation needed further elaboration.

In 1882 Luecke performed successfully the third gastrotomy. The fourth, fifth, and sixth cases were performed in the same year by Lauenstein Kocher (37) and Rydygier (72) respectively.

In 1883 Woelfler reported 2 modifications of his original operation. These were designed to overcome the difficulties encountered by Billroth in his first gastrotomy. In his first modification he suggested that that part of the lumen which belongs to the afferent branch should be so located that it will be covered for the greater part by gastric wall and that the efferent lumen

should communicate with the stomach through an opening having a diameter of 2 to 3 centimeters.

The second modification which he suggested was one in which reflux was placed on constriction of the lumen of the afferent limb by suture. Woelfler's ingenuity was exemplified later in his suggestion of still another operation. He detached the afferent limb from the efferent limb and inserted it a short distance lower down on the efferent limb. This formed a Y-shaped loop anteriorly. Later Roux made use of this principle but performed his operation on the posterior wall of the stomach. In the few operations that had been performed up to this date, no definite rule as to the length of the proximal limb of the intestinal loop was established. It was apparent that if per chance a loop of bowel close to the terminal ileum were applied to the stomach, the major portion of the digestive canal would be excluded from use. It was likewise apparent that if an extremely short loop were stretched around the transverse colon, it might cause obstruction of the colon or become obstructed itself. These considerations led to the performance of the first posterior gastrotomy.

On October 19 1883 Courvoisier performed a laparotomy for the removal of a pyloric tumor. The mass was irreducibly fixed and gastrotomy was decided on. The first loop of small intestine which presented itself appeared to be too distant from the stomach. Courvoisier decided to search for the duodenojejunal flexure. The omentum was severed transversely along the greater curvature of the stomach, an opening was made in the transverse mesocolon and the jejunum was found and pulled up. After isolating the site of anastomosis by silk sutures tied over split rubber tubes, one above and one below the isolated loop an opening 5 centimeters long on the antimesenteric margin of the bowel was made. The stomach was clamped off with a Gossauer clamp permitting a fold of the posterior wall of the stomach to remain exposed. This fold was also opened for a distance of 5 centimeters and both lumens were united. The entire operation lasted 2 hours and 50 minutes. The operation apparently was successful. On the eighth postoperative day the patient made the trip necessary to be presented at a meeting of the Swiss Medical Association at Olten. While there, she became ill, developed a fever and died on the thirteenth postoperative day. The autopsy showed a diffuse phlegmonous infiltration in the right rectus muscle and a diffuse peritonitis. A carcinoma of the pylorus was found. The anastomosis had healed perfectly. The stomach opening was in

Fig. 1

the middle of the greater curvature and in the jejunum it was just below the duodenojejunal flexure.

In 1884 Rydygier reported the first gastroduodenostomy performed for pyloric stenosis due

to a duodenal ulcer. It is interesting to note that of the 7 gastroduodenostomies thus far reported only 2 patients survived—one Woelfler's and the other Luecke's. This operation therefore seemed too formidable to suggest its use in the treatment

of a benign lesion. Rydygier's patient was 20 years of age. He had an ulcer of 4 years' duration. The patient was treated conservatively for his vomiting by the use of a stomach tube. Improvement however was not satisfactory and it was thought a pyloric resection was needed. At operation, it was found that the ulcer was in the duodenum and the abdomen was closed. Rydygier thought that if a gastro-enterostomy were done stagnation would occur in the duodenum. He felt, too, that in view of the high mortality following the operation it would be better to treat the patient with a stomach tube. Under medical management, the condition continued unabated and the patient lost weight. In desperation another operation was decided on. An anterior gastro-enterostomy was done and the patient made a satisfactory recovery. Later in the same year Rydygier reported 2 additional cases, both successful.

In 1884 Socin of Basel performed a gastro-jejunoscopy on a patient who had had a previous pylorotomy. In the same year Ranschoff performed the first gastro-enterostomy in the United States. By 1885 18 cases had been published.

On March 22, 1885 Billroth (5) attached the jejunum to the posterior wall of the stomach after passing it through an opening in the transverse mesocolon without perforating the gastrocolic ligament. Although the patient died following this operation Billroth was not content to discard this method completely but suggested further study of the technical difficulties he had encountered. Von Hacker of Billroth's clinic made anatomical studies on cadavers in an attempt to determine the most favorable site for anastomosing the jejunum to the stomach. A study of the structure of the mesocolon in a number of cadavers revealed several thin avascular regions through which the jejunum could be brought to the posterior gastric wall. Following these studies the operation was performed on patients in the clinic. The results obtained with this new technique were not encouraging. These results were due probably to the nature of the disease—"carcinoma cachexia"—rather than to the technique of the operation.

In 1886 Morse performed the first gastro-enterostomy in England.

In 1887 Rockwitz reported 8 consecutive successful cases and emphasized the importance of selecting suitable cases. With reference to indications, he advised that gastro-enterostomy be employed in cases of stenosis of the pylorus and of the duodenum where a resection could not be carried out. In cases of carcinoma, it was to be employed in the presence of extensive adhesions

or glandular metastases, since resection was then contra-indicated. Some of his rules for performing this operation are of special interest. He advised against the separation of adhesions and isolation and manipulations of intestinal loops because he believed that they lead to infection and weaken the patient. He also suggested that any loop might be used for the anastomosis, and referred to Nothnagel's experiment (57) for determining the direction of peristaltic waves.

In 1889, Pozzi performed the first gastro-enterostomy in France (49).

In 1892, Braun reported work which he did in 1884. He performed isoperistaltic application of the jejunum to the stomach as was later recommended by Rockwitz. Lauenstein advised entero-anastomosis if vomiting of bile and pancreatic juice occurred too frequently in the postoperative course of patients who had been subjected to gastro-enterostomy. He, however, suggested that any intestinal loop might be attached to the proximal limb of the jejunum to relieve this condition. This was objected to by Braun because in some instances the terminal ileum was used with very unsatisfactory results. It was Braun's conclusion that when entero-enterostomy was indicated it should be performed between the afferent and efferent limbs of the loop used for the gastro-enterostomy. Jaboulay in 1892 suggested an anastomosis of the distal loop with the third portion of the duodenum so that the pancreatic and biliary juices would be carried away from the stomach.

One of the most troublesome complications of gastro-enterostomy was observed in Billroth's first case. This was the occurrence of a postoperative train of symptoms which have since been designated as "vicious circle" (17). The procedures suggested by Woelfler, Braun, Lauenstein, and Jaboulay were for the purpose of avoiding or relieving this complication. The principle underlying these methods was the prevention of reflux of intestinal contents through the gastro-enterostomy stoma.

In 1897 Roux reported his experience with 50 gastro-enterostomy cases performed as follows: Anterior antecolic, 8 cases; posterior retrocolic, 7 cases; Kocher's valve, 3 cases; retrocolic *en Y*, 29 cases; anterior antecolic *en Y*, 3 cases; anterior retrocolic *en Y*, 1 case; anterior retrocolic, 1 case. His mortality was 30 per cent. In the 29 cases in which he performed the posterior *en Y* operation, the mortality was 20 per cent. He preferred the posterior *en Y* operation because the opening was made in the most dependent part of the stomach and there was no spur, kink, or valve. In this operation, there was also no pressure on the colon.

Fig. 1

The posterior retrocolic operation grew in favor and attracted the attention of many surgeons. It received a further stimulus through the anatomical studies made by Petersen on the relationship between the highest portion of the jejunum and the lowest portion of the stomach. He found that

it was possible to anastomose the jejunum with the stomach close to the duodenojejunal flexure without much tension. This obviated the necessity of a proximal loop and made it unnecessary to perform the *en Y* operation which was designed to accomplish the same purpose. In 1901,

Petersen's work was published from Czerny's clinic and its importance was recognized by surgeons throughout the world. It was adopted by the Mayo in this country, by Moynihan in England and by other large clinics. Aside from some minor modifications, the operation of Petersen is in substance the operation that is performed today.

The interval between 1881 and 1901 saw a group of operations that demonstrated the ingenuity of the surgeons of that day and the accompanying illustrations portray a number of these interesting procedures. In addition to the mechanical hook up difficulties experienced, there were the difficulties of avoiding infection and of maintaining the patency of the stomata. The danger of infection in those early days contributed liberally to failure. The incidence of infection was high because the operation was done commonly for malignant pyloric obstruction in the presence of a diminished or absent acidity of the gastric contents. Even today these cases do not fare as well immediately after operation as do those cases in which a benign obstruction is present. To overcome the possibility of infection, operations were devised from time to time in which the anastomosis was performed without opening the mucosa at the time of operation. Thus McGraw (45) in 1891 used an elastic ligature which was designed to cause necrosis eventually of the encompassed tissues and establish an opening between stomach and jejunum. Similarly Postnikow and Podreza used heavy silk ligatures. Souligoux used an angiotribe. Boari and Paul used caustics applied to the mucosa which caused it to slough through at a later date.

There were many failures due to closure of the stoma some time after operation. It was believed that this might be avoided by the use of artificial substances which would splint the mucosa until healing took place and at the same time insure the patency of the opening. Thus Senn described the use of decalcified bone plates in 1888. Robinson advocated raw hide plates in 1890. von Baracz used turnip plates in 1893 and during the same year Murphy used his famous balloon. In 1893 Mayo-Robson used the bone bobbin and in 1900 Credé advocated perforated silver plates. Many modifications of each of these methods have been recommended but practically all of these procedures have been discarded by present day surgeons.

The continued use of gastro-enterostomy has stimulated an interest in the anatomy and physiology of that portion of the gastro-intestinal tract related to this operation. Some of the pertinent facts will be reviewed briefly.

ANATOMY AND PHYSIOLOGY

The stomach is a muscular organ divided anatomically into 4 parts: fundus, body, antrum, and pylorus. The latter is not far from its lowest point and lies nearly in the midline of the body. As the stomach distends, it becomes more nearly horizontal by the elongation of the greater curvature. The pylorus passes to the right of the midline and relatively passes above the greater curvature. The gastro-epiploic artery lies at some distance from the greater curvature when the stomach is empty and sends its gastric branches to the anterior and posterior gastric walls. The arrangement of the blood vessels enables rapid distention of the stomach without interference with the blood supply (38). The lesser curvature is more fixed in position and can be divided into 2 parts: the perpendicular portion, which drops nearly vertically from the right margin of the cardiac orifice, somewhat to the left of the midline, and the horizontal or slightly curved portion, which turns sharply to the right and ends at the pylorus. This division of the lesser curvature corresponds to the line of separation between the antrum of the stomach to the right and the body of the stomach to the left.

With these gross external anatomical divisions of the stomach, there are internal anatomical differences. Bisection of the stomach through the greater and lesser curvatures shows that the antrum has a mucosal lining which is rougher, exhibits fewer rugae, and has a correspondingly lighter (pinker) color than the mucosal lining of the body of the stomach. The thickness of the wall in the antrum is greater and this thickness is due principally to the increased amount of muscle tissue, especially the circular fibers.

These gross anatomical differences are associated with physiological differences. The body of the stomach is the storing and digesting portion of the stomach. Here the greatest activity is shown by the mucosa whose numerous folds afford a large secreting surface. The antrum, conversely, is the active motile and grinding portion of the stomach. Here the greatest activity is exerted by the musculature. In the antrum the peristaltic waves arise approximately 4 times as frequently as they do in the body of the stomach. The difference in the muscular activity of the 2 portions of the stomach accounts also for the marked variations in intragastric pressure. The pressure in the fundus is low as compared to that in the antrum but even here there occur marked fluctuations.

In 1887 von Pfungen measured intragastric pressure on a boy with a gastric fistula. The pressure in the fundus varied only from 5 to 10 millimeters of mercury while in the region of the pylorus

Fig. 3

rus it varied between 40 and 50 millimeters. Moritz also found that in the fundus the variations of pressure were from 2 to 6 centimeters of water while in the pyloric region the pressure rose to 60 centimeters of water.

The irritability of the antrum is greater than that of the body. Any trauma to the antrum will usually result in spasms of great intensity while this phenomenon is not noted in the body. Ivy has shown that when the antrum is traumatized in making a Pavlov pouch, the intensity of the spasm may be so great that the animals will die of starvation from the spastic obstruction. This does not occur however when the surgical procedure is confined to the body of the organ. The distribution of the vagus and sympathetic nerves, those especially associated with muscular activity is probably greater over the antrum than over the body of the stomach. C. H. Mayo (37) records the fact that X-ray observations have shown that an ulcer that is situated in the antrum will produce more spasm than an ulcer that is located at the pyloric end of the stomach or of the duodenum.

The purpose of this brief exposition of the anatomy and physiology of the stomach is to point out the marked differences that exist between the antrum and the body—differences that are so great that one may consider them functionally as 2 independent organs. In granivorous birds there are present 2 distinct divisions of the stomach (22). One is known as the secretory stomach and the other the motor stomach (Fig. 3). While these divisions are not so pronounced in mammals yet in some of the lower forms the divisions are easily recognized. These differences may also account for the conflicting reports in experimental and clinical work. In 1905 Cannon and Blake showed that if the pylorus were patent the gastric contents would not leave through the artificial stoma but would leave by way of the pylorus. Berg made similar observations and reported them in 1913. Their experiments were performed on dogs and cats. It has been repeatedly shown that in humans this is not always true. Numerous X-ray examinations of patients with gastro-enterostomies show that in a high per cent of cases the meal will leave through the gastro-enterostomy stoma.

even though the pylorus is patent (38). In many cases the meal will leave by way of both openings. To be sure that the food would leave through the newly formed stoma Kelling in 1901 and Mayo (42) in 1902 suggested that the pylorus be excluded by plication without division of its continuity. A similar interruption of the pyloric lumen was carried out in 1895 by von Eselsberg who in a case of irremovable pyloric carcinoma, divided the stomach proximal to the tumor and then closed both ends by suture. This procedure was designed not so much to insure the passage of the gastric contents through the new stoma as to prevent the spread of the carcinoma in the direction of the new stoma. In 1914 Hartman showed that the location of the stoma had much to do with the path taken by the meal in leaving the stomach. If the stoma is placed too far away from the pylorus i. e. far up on the body of the stomach the new outlet is so remote from the driving portion of the stomach that no sufficient increase in intragastric pressure can possibly influence the movement of food through the new opening. Hartman quotes Tuffier who states "I remind you how easy it is to observe on a dog, making use of *N. rays*, that everything passes through the pylorus, because we know when operating on a dog that the new pylorus can only be placed at a distance of 25 centimeters from the normal pylorus and not less. Those who placed the stoma nearer the pylorus observed different *N. ray* findings."

Thus we are led to a discussion of the position the stoma should occupy in the operation of gastropylorostomy. It would seem from the foregoing that the only logical location would be at a point just proximal to the antrum. Thus it would lie outside of the grinding highly active, irritable portion of the stomach and yet at about the most distal portion of the body of the stomach. This location also would receive the benefit of the greatest intragastric pressure without interfering with the activity of the antrum. The location of the stoma in the antrum is obviously illogical since it acts in itself as a trauma to this highly sensitive portion of the stomach, interferes with its contracting ability and by its spasm may occlude the lumen of the new stoma. The location of the stoma in the body of the stomach will of course decrease its suitability in direct proportion to its distance proximal to this juxta-antral line.

With the stoma located just proximal to the antrum, the direction would of necessity be vertical, i. e. running from the lesser to the greater curvatures. The line along which the stoma should be placed is described by Moynihan (54) as being in line with the esophagus. It will be found that

when traction is made on several points along the greater curvature, a fold will appear at one point which is in line with the right border of the esophagus. The stoma should be placed about 1 inch proximal to this line.

The size of the stoma should, of course, be adequate. Experience has shown that an opening approximately 2½ inches in length in the jejunum and stomach is sufficient for satisfactory evacuation of the stomach.

There are apparently valid objections to having the long axis of the stoma placed in the longitudinal direction of the stomach. Such an opening produces a trough which results in the constant presence of residual gastric contents below the level of the stoma. Incidentally a longitudinal incision along the greater curvature results in the cutting across of many branches of the gastropyloric artery at the site of the stoma while a vertical incision runs almost parallel to these vessels. Since drainage is one of the most beneficial results of this operation, the stoma should run down to the greater curvature so that the lowest point of the stoma lies at the lowest point of the stomach. Mayo in 1905 was so impressed with this detail that he advised carrying the posterior opening past the greater curvature on to the anterior wall of the stomach.

Moynihan early in his work suggested that the opening in the posterior wall of the stomach be inclined downward and to the right (isopneustic). Mayo (40) however advocated that the jejunum be applied obliquely to the left almost at a right angle to Moynihan's line. The basis for this suggestion was that normally the jejunum lies to the left of the vertebral column in a fossa above the left kidney. Further observation led Moynihan (52) to state

"To say that the jejunum takes a certain line normally from the flexure is probably neither accurate nor reasonable. The ligament of Treitz suspends the jejunum thus allowing it to go to the left or right without twisting. One line is probably as good as another or any line between them as good as either provided no twist is made in the gut. Just as there is no natural direction of the jejunum so there is no best line for the anastomosis."

The location of the stoma in the small intestine should be on the antimesenteric side of the jejunum close to the ligament of Treitz. The anatomical investigations of Petersen in Czerny's clinic at Heidelberg and the recent investigations of MacLeod are of interest because they point out the relationship that exists between the first portion of the jejunum and the posterior wall of the stomach. MacLeod noted that that part of the jejunum which lies below the duodenal flexure as

Fig. 4.

it passes either through the transverse mesocolon or immediately between it and the posterior abdominal wall is constant in position regarding its level and lies either in front of or to the left side of the third lumbar vertebra. In some cases of general visceroptosis it was placed as low as the lower border of the fourth but it was usually well above the level of the greater curvature. The position

of the lowest part of the stomach is not constant but lies somewhere on the greater curvature between 2 points, one of which lies $1\frac{1}{2}$ inches proximal to the pylorus and the other 2 inches to the left of the midline. He further demonstrated that by applying traction on the greater curvature the lowest point of the stomach can be located. This usually lies to the left of the mid-colic artery but

in a few it is to the right. The jejunum where it crosses the greater curvature runs sharply downward, in most cases across or just to the right of the most dependent part of the stomach and in a lesser number of cases slightly obliquely to the left. MacLeod found that in every case there is ample room for anastomosis with a satisfactorily large stoma.

Mikulicz also suggested an operation with a very short loop so as to avoid the afferent limb which was responsible for the train of symptoms known as vicious circle. He demonstrated to the Mayos at Rochester in 1903 a method of application of the jejunum to the stomach that was based on the important observation that the duodenojejunal angle is always above the greater curvature of the stomach and that the jejunum has a vertical course downward where it crosses the greater curvature. In this work Mikulicz used a transverse incision in the jejunum. He effected an anastomosis with the stomach which was satisfactory except for the fact that the transverse opening in the jejunum was too small for adequate drainage of the stomach. This has been abandoned in favor of the longitudinal incision in the jejunum—a procedure which was emphasized by Petersen in 1901.

Occasional variations in the anatomy of the stomach, duodenojejunal angle, and transverse mesocolon may influence the exact location of the site of anastomosis. Fauchild has emphasized the transverse position of the stomach in a stout individual as contrasted with the longitudinal position in the slender ptotic individual. The jejunum may have either a long or a short mesentery or it may arise (rarely) below the stomach or it may arise at a considerable distance to the left. Thus it seems, the best plan to follow is that suggested by Moynihan and emphasized by Wilkie that the relation between the jejunum and stomach be determined within the abdomen at the time of operation before the anastomosis is made so that no distortion is produced by the anastomosis.

Considerable attention should be given to the selection of the site of the opening in the transverse mesocolon in performing posterior gastrojejunostomy. Within its folds lies the colica media artery whose injury may result in necrosis of the transverse colon. The opening in the transverse mesocolon should be made in an avascular area to the left of this important vessel. In stout individuals the transverse mesocolon may be short, while in slender individuals it may be long. Hence its relation to the stomach and jejunum should be determined with the organs in the abdomen before anastomosis is attempted. Traction by a short

mesocolon may seriously interfere with the functioning of the new stoma. The opening in the mesocolon permits communication between the lesser and greater peritoneal cavities.

Herniation of viscera from the greater sac to the lesser sac may occur if the edges of the opening in the mesocolon are not fixed to the stomach or jejunum. In the early days of this operation, the opening was occasionally sutured to the stomach because it was learned that contraction of the opening about the stoma could occur (43). It was found later that herniation into the lesser peritoneal cavity was common when this suturing was not done. Von Hacker originally sutured the edges of the slit to the stomach and even as late as 1901 Robson and Moynihan suggested that this might be advisable in order to prevent contraction of the slit with consequent narrowing of the jejunum as was noted by Czerny. In 1903, Moynihan (53) had his first experience with herniation into the lesser peritoneal cavity in a case in which he had failed to close the opening in the transverse mesocolon. Subsequently he advocated that this be done in every case. A similar experience by W. J. Mayo (39) resulted in further emphasis on the importance of this procedure. While Moynihan suggested that the slit be sutured to the jejunum, there is a possibility that this may result in obstruction as was recently reported by Torrance. Mayo suggested that the slit be sutured to the site of the anastomosis but in 1912 (39) he reported that in 2 cases where a fat mesocolon was encountered, a constricting band developed which required a second operation for its relief. In his later cases, no difficulties were encountered when the raw edges of the slit were tucked into the lesser peritoneal cavity. This was done by a special application of the suture slightly removed from the raw edge thence through the stomach and jejunum where they lie approximated by suture.

MacArthur offered an important suggestion when he advocated that the slit be sutured to the stomach before the stomach was approximated to the loop of the jejunum for anastomosis. It is obvious that following the anastomosis, the posterior aspect of the gastro-enterostomy is not easily accessible and undue traction may be necessary in order to place the posterior sutures. When clamps are used, he advises that the sutures be placed after the clamp is applied to the stomach and before this clamp is approximated to that on the jejunum.

The use of clamps to facilitate operations on the intestinal canal was described by T. Kocher (58) in 1880. He devised these instruments for intesti-

nal resection but their use for other surgical procedures in intestinal work was made apparent. In 1893 W. A. Lane made use of clamps with curved flat blades that were devised by T. Smith for abdominal operations. By 1895 the use of clamps became well established and they were illustrated in the textbook of surgery by Doyen. In 1900 H. Littlewood of Leeds described the use of rubber covered Doyen clamps in performing gastrojejunostomy. Moynihan early made use of them and it is due probably to his extensive writing that they have become popularized. His demonstration of their use to the Mayos in 1903 at Rochester was the first time they were used in this country. It should be noted however that clamps are not considered an absolute necessity and many surgeons prefer to effect the anastomosis without their use. In obese individuals, those with a short transverse mesocolon or a short mesentery of the jejunum, the use of clamps often is made almost impossible.

The type of suture material used in gastrojejunostomy has been a controversial subject for some time. Increasing experience has shown that the use of absorbable material is probably most satisfactory. The presence of non-absorbable suture material which may ulcerate through the wall of the viscus and result in secondary hemorrhage or chronic ulceration has led to the suggestion that this type of suture be discarded (77). In the experience of many surgeons there have occurred instances when on reopening the stomach non-absorbable suture materials were found to hang from the site of anastomosis in the lumen of the jejunum. There are some who still prefer the use of silk or linen for all layers of the anastomosis. Others are divided in their selection, some use catgut for the mucosa and linen or silk for the seromuscular layer or vice versa. The use of interrupted non-absorbable sutures to re-enforce the anastomotic sites of particular stress has been rather widely adopted. These are placed as interrupted sutures in the seromuscular layer. More liberal use of these interrupted sutures is made in carcinoma of the stomach or other cachectic states.

The depth of penetration of the suture is of importance. The toughest layer of the intestinal canal is the submucosa and it is into this layer that the seromuscular suture must penetrate if it is to serve its purpose best. It is practically impossible to make this an aseptic suture since the mucosal glands dip into this layer to such an extent that an adequate stitch must of necessity penetrate some of these glands, at least in the jejunum. It has been aptly stated by Sweet that more lives are lost because the suture did not penetrate deeply

enough than because of infections resulting from a deep penetration of the suture. The peritoneum may well care for the slight infection engendered by a septic suture but may be powerless against a leak occasioned by the separation of the approximated viscera which occurs as a result of inadequate suturing. It has been found satisfactory to ligate the vessels traversing the submucosa at the site of the stoma in the stomach after the superficial layers have been incised. The larger vessels must be ligated if postoperative hemorrhage is to be consistently avoided. The lock stitch which usually is employed as a hemostatic suture, although adequate to control the capillary oozing of the incised mucosa of the stomach and jejunum is not adequate for hemostasis of the larger gastric vessels that are severed. This is especially true when clamps are used to fix and approximate the loops of stomach and jejunum for anastomosis. As soon as the clamps are removed and the viscera released from their fixed position of extension, muscular contractions tend to decrease the size of the stoma but the fixed suture now has redundant loops which no longer compress the vessels within their grasp.

It should be noted also that suturing should be for the sole purpose of making adequate approximation of the tissues, thus permitting nature to effect a healing of the approximated structures. When excessive traction is made in placing the sutures, strangulation of the tissues ensues with resulting necrosis and sloughing. This may result not only in secondary hemorrhage but also in leakage into the peritoneal cavity.

At the time of incision into the stomach and jejunum the free secretions should be removed at once by gentle sponging. These secretions are rich in enzymes, which if allowed to be spread about may favor rapid absorption of the sutures. When the placing of sutures has been completed it is essential that there be no oozing of blood from the suture line and that all raw surfaces be adequately covered. This will prevent the formation of scar tissue which might constrict or distort the stoma. Before the operation has been concluded a careful inspection and survey should be made to establish (1) the correct mechanical arrangement of the anastomosis (2) the absence of twists or kinks (3) the patency of the stoma. Before the abdomen is closed the viscera are so arranged that the new stoma hangs free to the left of the vertebral column in order that the site of anastomosis will not be compressed between the anterior abdominal wall and the vertebral bodies. The greater omentum is replaced over the under surface of the anterior abdominal wall and closure of

the abdomen is made by layers without drainage. The posterior sheath of the rectus muscle and peritoneum may be closed by a continuous suture but the anterior layer of the rectus sheath had probably better be closed in most instances with interrupted sutures.

DRAINAGE OF THE PERITONEAL CAVITY AND INTESTINAL OBSTRUCTION

ACUTE intestinal obstruction is a very grave malady. Exclusive of strangulated hernia the average mortality is around 50 per cent. Adhesions are the largest single factor in bringing about this malady and the adhesions are due chiefly to either infection or drainage material left temporarily in the peritoneal cavity. One of the most difficult decisions that a surgeon is called on to make is to differentiate between paralytic ileus and mechanical obstruction as a post-operative complication of the acute surgical abdomen complicated by peritonitis and treated by drainage. Operative procedures for paralytic ileus are usually not only futile but harmful, but to fail to relieve acute mechanical obstruction promptly is to rob the patient of his chance of life. Altogether the problem is a most harassing one.

Closure of the infected abdomen without drainage is against tradition custom and common sense on the other hand, the placing

of drainage material where it comes in contact with loops of small intestine is to invite obstruction, either as an early or late mishap or to condemn the patient to an uncertain period of partial disability caused by angulation due to adhesions and these adhesions are often the one thing that spoils an otherwise successful operation.

There is experimental and clinical evidence that drains left in the peritoneal cavity are soon sealed off and there is also abundant proof that the peritoneum is a very efficient tissue in taking care of its own difficulties. This is especially true of infections, provided the cause of the contamination is removed and the door closed to further leakage. When gynecologists began to close the abdomen after removal of acutely infected pelvic organs, many surgeons were aghast and it soon became evident that leakage following intestinal suture was more likely to occur if drains came in contact with the suture line.

Drainage material placed in the peritoneal cavity cephalate to the level of the transverse colon is not so likely to cause obstruction because the jejunum and ileum are usually found caudal to this level. For this reason acute obstruction is not a common complication of drainage following operations on the biliary duct apparatus, the liver pancreas, duodenum, or stomach.

The solution of the problem, in part, is to place as little drainage material as possible where it is likely to come in contact with coils of small intestine. In draining a walled-off peritoneal effusion the risk of obstruction is not great. To close the abdomen, however in the presence of peritonitis seemed a fool

hardy thing to do, but less and less drainage was being used and, being harassed by the imminence of obstruction the writer several years ago, began to close the abdomen where early peritonitis was present at operation. My opinion is based on 90 patients with early diffuse peritonitis occurring in about 600 cases of appendicitis. A satisfactory classification of peritonitis from the standpoint of treatment is to divide these cases into three groups.

1 Early peritonitis whether localized spreading or diffuse, whether serous, seropurulent, or purulent, irrespective of the infecting organism and without regard to whether the appendix which is usually at fault is catarrhal thrombotic, gangrenous or perforated. The essential thing in this group is that the peritonitis is an early one—that is that the gut is still smooth and glistening and not markedly distended or discolored and that the coils of intestine are not adherent. In this group we carefully remove the appendix, with a minimum of handling through a McBurney incision suck out the liquid exudate and close the peritoneum without drainage. We usually drain the subcutaneous fat. We have had no serious mishap in this group.

2 Localized collections of pus within the peritoneal cavity so called pelvic, appendicular, subhepatic or subphrenic abscess. These walled-off effusions are drained. There were 20 of them and all recovered.

3 Late diffuse peritonitis with widespread adhesions between the different abdominal viscera surrounding multiple pockets of pus distended, discolored, and cedematous intestine, a board-like abdomen rapid pulse, anxious features dehydration and disturbance in the acid base balance. These were all drained and all of the fatalities were in this group 10 deaths in 30 patients.

This classification gives a good working basis and corresponds fairly well with the

British manner of indicating the seriousness of acute appendicitis by using the time factor 1 day, 2 day, 3 day etc. The peritoneum has a very remarkable defensive mechanism which apparently reaches its maximum efficiency when not disturbed by wide incisions, rough or prolonged handling, or the presence of drainage material, provided the cause of infection is removed and postoperative leakage controlled.

ARTHUR M. SHIPLEY

CARCINOMA OF THE BLADDER

THE successful treatment of carcinoma is dependent on its early recognition its situation, its cell differentiation its accessibility, and on its tendency to metastasize. Carcinoma of the bladder is unique in that all of these factors apply very definitely yet distinct progress in its management can hardly be said to have occurred for the past several years.

Symptoms of the disease become manifest soon after its inception, but the patient often disregards Nature's warning because of fear or timidity. It is difficult to understand why a person will consult his physician if blood is vomited but will attribute blood in his urine to a cold to bad food recently eaten or to some unusual strain, yet, though it is not diagnostic, bloody urine is one of the earliest signs of carcinoma of the bladder. Statistics in some institutions show that the average duration of symptoms prior to admission for treatment is 2 years. Obviously if this period is not reduced, the number of inoperable malignant lesions will continue to increase. If small lesions amenable to transurethral surgery are disregarded it is a matter of record that approximately 25 per cent of the major malignant lesions when first seen are inoperable.

Cell differentiation in a vesical carcinoma is a reliable index in estimating the ultimate

prognosis and is an aid in formulating the method of surgical attack. Tumors whose cells are highly differentiated are growing slowly so that there is not the tendency to invade the wall of the bladder or to extend beyond it. In fact many of such lesions are papillary or pedunculated and these lend themselves particularly well to transurethral attack. Likewise some of the more extensive lesions can be treated unless there is some other complicating condition such as obesity associated with recent coronary thrombosis. In the latter instance I feel that one can remove the growth more completely by the suprapubic or transvesical approach. Furthermore, a more satisfactory investigation of the vesical wall and adjacent mucosa can be made and the presence or absence of metastasis although rarely seen with this grade of carcinoma, ascertained. Accordingly the prognosis can be more wisely estimated.

Tumors whose cells are less differentiated are more malignant and as a rule invade the wall of the bladder early. They tend to ulcerate and produce considerable bleeding and they frequently are associated with necrosis and infection. Malignant lesions of this type in any hollow viscus are always a serious surgical problem and the prognosis must usually be guarded. The problem immediately becomes more complicated when the lesion involves the natural orifices of associated organs. As an example a small ulcerating malignant lesion of the pylorus may easily be resected but it is a much more difficult and serious situation should even a smaller lesion involve the ampulla of Vater. The same is true in the urinary bladder most unfortunately however these ulcerating highly malignant lesions are often situated around one or both ureteral orifices and the internal sphincter of the bladder. When the malignant lesion involves both ureters it probably is inoperable.

Involvement of a ureter immediately brings up the question of conservation of the affected kidney. Reimplantation of the ureter following segmental resection increases the mortality approximately 20 per cent but this mortality can be reduced by 50 per cent if the ureter is only ligated and dropped back. The latter procedure is applicable only when there is a sound kidney and free ureter on the opposite side. The fate of the kidney with a reimplanted ureter is much debated and offers an excellent field for investigation.

Randall recently observed that a kidney may cease to function if a malignant lesion is situated near the ureteral meatus. The answer to the high mortality following reimplantation may be partly contained in Randall's observation. If this observation is confirmed by others early diagnosis and treatment should assume increasing importance since a high percentage of rapidly infiltrating tumors as well as highly differentiated tumors occur in close proximity to the ureteral meatus. In fact, one of the most frequent and vulnerable points of origin is just above the meatus and directly over the intramural portion of the ureter so that early partial obstruction of the ureter at least, may occur although the meatus may be free from involvement. The rapidity with which involvement occurs depends largely on the cellular differentiation.

Fortunately many vesical tumors are essentially highly differentiated frequently multiple and pedunculated. Transurethral resection of the tumor and electrocoagulation of the base or the application of radium as indicated are the rule for such lesions. Some of the less differentiated more invasive tumors may occasionally be adequately handled by the same principle but the prevailing opinion of urologists in general is that these lesions should be attacked by the transvesical approach, since the tumor is more accessible and its local re-

removal or destruction is therefore more likely to be complete. This is particularly true if the ureter is involved and segmental resection is indicated. Tumors involving the dome and posterior wall are also quite accessible and lend themselves readily to resection.

It would be a distinct advantage in formulating the type of treatment were it possible to ascertain clinically the presence or absence of metastasis. If metastasis has occurred in the majority of cases only palliative treatment is indicated. The frequency of metastasis in carcinoma of the bladder is about the same as for carcinoma elsewhere and according to Spooner conforms to the plan set forth by Broders, in his classification of epitheliomata, that the less differentiated tumors metastasize early. He has found that the incidence at necropsy of metastasis of vesical carcinomata is 29 per cent which indicates that it is much more common than is generally believed which is contrary to the opinion that vesical carcinomata metastasize late.

From the surgical point of view these findings are extremely important, though somewhat discouraging because rarely can an extensive operation for carcinoma of the bladder be done with removal of the involved lymph nodes without a high mortality. Future development in roentgen therapy may

offer a more hopeful prognosis. Inability to determine clinically the presence of metastases is stressed by Spooner. He noted that in 65 per cent of cases in which metastasis was present the condition was regarded as amenable to surgical treatment, when dealing with a large infiltrating lesion therefore the foregoing data are suggestive at least that the peritoneal cavity should be opened and careful exploration performed before a radical resection is carried out which at best is only temporary if lymph nodes are involved. The clinical significance regarding the possibility of metastasis, malignancy of high grade and a large lesion should be emphasized in a case with symptoms present for one year.

The value of a follow up system in cases of carcinoma of the bladder cannot be overestimated. Recurrence may take place following any method of surgical treatment but if the recurring lesions are discovered routinely before they produce symptoms, many of them can be destroyed transurethrally and a good result obtained. For instance in a recent series of 67 cases in which patients had local recurrences and returned regularly at stated intervals for examination 75 per cent are alive and free from symptoms referable to the bladder and have been for 5 or more years.

VIRGIL S. COUNSELLER

MASTER SURGEONS OF AMERICA

CHARLES BEYLARD GUERARD DE NANCRÈDE

On December 30 1847 Charles Beylard Guerard de Nancrède, was born at Philadelphia, Pennsylvania the son of Thomas Dixie Nancrède wholesale importer and May Elizabeth Nancrède nee Bull he died April 12 1921 at Ann Arbor Michigan.

Dr de Nancrède's paternal ancestors were of French Huguenot origin. His grandfather Paul Joseph de Nancrède was born in Hericy France, and came to the United States as a lieutenant in the French Army. He served under Rochambeau and was wounded at Yorktown. He emigrated with his wife to the United States in 1785 and became professor of French at Harvard where he taught for 10 years, from 1787 to 1797.

The early education of Dr de Nancrède was in private classical schools and in a military school at the latter he was honored by being selected as one of the cadets who fired the salute at Lincoln's funeral. He later entered the University of Pennsylvania and graduated from the medical department with the degree of doctor of medicine in 1869. Although primarily a medical man and devoted to his work, he had a fondness for art and music. He was particularly interested in painting and once said "I would have made a better painter in the Fine arts than a surgeon."

His work in physiology anatomy and in the eye service at the University of Pennsylvania helped to broaden his medical knowledge. He had considerable training in surgery of the eye and did some major eye surgery where speed was essential, without the aid of an anæsthetic this training helped develop his exceptional lightness of touch and speed in surgical technique.

He was one of the first surgeons in Philadelphia to operate for bullet wounds of the stomach and intestine and later for appendicitis. One of the first operations for the removal of the appendix was done in Philadelphia at the Episcopal Hospital where he was an attending surgeon.

Later he became surgeon and clinical lecturer on rectal and general surgery in the Jefferson Hospital Medical College. He was also attending surgeon at St. Christopher's Hospital for Crippled Children and at the Philadelphia Poly clinic where later he was made emeritus professor of general and orthopedic surgery. He was one of the first surgeons to devote time and study to the diag-

CHARLES B G DE NANCREDE
1847-1921

nosis and treatment of brain abscess and cortical epilepsy. He was a persistent advocate of Listerism and, with Drs Keen and Mears has been more than once accredited before the Academy of Surgery as chiefly responsible for establishing this practice in Philadelphia.

At the time of his coming to Ann Arbor the antiseptic era of surgery had begun. Throughout his early days at Ann Arbor he fought not only for antiseptic surgery but for aseptic surgery as well. We who knew him as students will always remember the emphasis he placed on the necessity of practicing aseptic surgery. In addressing the medical students when he came to Ann Arbor as professor of surgery it is reported that he said "Gentlemen we will continue to operate on patients in this hospital. There will probably be many deaths. Where there is a death, do not blame the walls, look elsewhere for the cause."

Prior to accepting the chair of surgery at the University of Michigan he had been striving to enlarge his experience in every branch of the healing art. His untiring interest in other branches of medicine was always impressed upon his students—"I am not a surgeon but a medical man who operates." His activities were not limited to Ann Arbor as he held the chair of surgery and of clinical surgery at Dartmouth Medical College from 1900 to 1913 where he gave his course during the summer.

The recognition shown him by his colleagues is indicated by the honors which came to him. He was president of the American Surgical Association and vice president twice, he was major and chief surgeon United States Volunteers, third division, Second Army Corps during the War with Spain and served in the Santiago campaign in Cuba with the Fifth Corps. He was made a brevet lieutenant colonel for services to the wounded under fire July 1, 1898 and later was commissioned as a major in the Medical Reserve Corps, United States Army but was not called to active duty in the World War. He was twice president of the Washtenaw County Medical Society, president of the Northern Tri State Medical Society, corresponding member of the Royal Academy of Medicine, Rome, Italy, member, recorder, and editor of the transactions of the Pathological Society of Philadelphia, member and secretary of the Philadelphia County Medical Society, member of the Pennsylvania State Medical Society, the Ohio State Medical Society, the Colorado State Medical Society, the American Medical Association, the American College of Surgeons, the Detroit Surgical Society, the International Society of Surgery, International Congress at Madrid, Spain, and of the Philadelphia Academy of Natural Science. Aside from the degrees of A.B. and M.D., the following honorary degrees were conferred upon him—M.A. University of Pennsylvania, M.D. and LL.D. Jefferson Medical School, and A.M. and LL.D., University of Michigan.

Dr de Nancrède was a contributor to the *International Cyclopedia of Surgery*, the *Cyclopedia of the Diseases of Children*, Burnett's *Cyclopedia of Diseases of the*

Nose and Throat Dennis *System of Surgery* Parks *System of Surgery* by American authors, the *American Textbook of Surgery* and Bryant and Buck's *American Practice of Surgery*. He was the author of *Essentials of Anatomy* and of *Principles of Surgery*. The last a unique work, contained such expressions as "*vis a tergo*" "*pabulum*" "*locus minoris resistentiae*". The ideas expressed in this book can be studied with great profit today. He published also numerous monographs and papers on anatomical pathological and surgical subjects. He carried out research on the nature of the gastric juice of the dog, the effect of blood letting on inflammation, the sterilization of catheters and the rate of absorption of catgut. The personal attention which he gave to his patients no doubt deprived him of sufficient leisure to make his contributions to medicine even more voluminous.

He never spared himself or others where the welfare of the patient was concerned. Night calls had no terrors for him if the welfare of the patient was concerned. He frequently visited the hospital at night rather than leave this responsibility to his capable assistants. He was in fact, an individualist.

He was practically ambidextrous and exceedingly deft in his light touch, almost dainty with his small delicate hands. He was very exacting of himself and his staff in the thoroughness of examination of the potential surgical patient by inspection palpation auscultation and all the other means available to achieve a diagnosis. Speed in surgical technique combined with thorough anatomical knowledge marked his generation of surgeons and he was an outstanding example.

On June 3, 1872, he was married to Alice Howard Dunnington of Baltimore Maryland. Nine children were born to them and at the time of his death he was survived by his wife and five children. He was an affectionate indulgent father and very much devoted to his home and family. He had no ambitions along social lines, possibly because he had himself achieved such prominence that he realized the futility of such ambitions.

He was punctilious in his personal appearance, always maintaining an erect military bearing. This latter personal characteristic was undoubtedly developed during his early training and subsequent military duty. Direct in his personal relations with men, he had a high sense of honor and ethics, and a tremendous personal courage. He scorned any chicanery or political maneuvers which tended to develop enemies and he was somewhat contemptuous toward those who failed to agree with his policies. He was opinionated and seemingly somewhat intolerant of the view of others who differed with him, yet he was kindness itself and extremely tolerant of his students and of the younger men on the staff. They respected his knowledge and were very fond of him personally.

The late Dr. Victor C. Vaughan wrote in *A Doctor's Memories* of Dr. de Nancrede: "I cannot overestimate the services rendered to the University by this man. Dr. Reuben Peterson at a meeting of the Washtenaw County Medical

Society, June 1921, paid a glowing tribute "to the valuable and distinguished services of the great surgeon Dr de Nancrède "

One need only mention his high rank as professor of surgery, clinical surgery and director of the surgical clinics at the University of Michigan from 1889 to 1917, to show that he was universally recognized. His interest in surgery and his devotion to his patients endeared him in the hearts of all who had the privilege of attending the University Medical School during his time. One could not help but be stimulated by his enthusiasm. His influence will long remain in the minds of his students and it may well be said that his life and work represent the true ideal fulfilled.

GROVER C. PENBERTHY

EARLY AMERICAN HOSPITALS

THE CHARITY HOSPITAL OF LOUISIANA

A. E. FOSSIER, M.D. NEW ORLEANS, LOUISIANA

(O)NE hundred and ninety nine years ago and approximately 18 years after the founding of the City of New Orleans by Bienville, the *Charity Hospital of Louisiana* was founded. It is the oldest institution of its kind in the United States.

The sailor Jean Louis a resident of New Orleans, died at noon on the 21st day of January 1736. He left a holographic will in which the following was specified:

My debts having been paid and the above provisions having been executed, a sale shall be made of all that remains, which, I bequeath to serve in perpetuity to the founding of a *Hôpital for the Sick of the City of New Orleans*, without any one being able to change my purpose, and to secure the things necessary to succor the sick.

A site was immediately chosen at the extremity of the town which Governor Miros stated stood upon a portion of the ground allotted to the City's fortification and today corresponds to the square bounded by Rampart Basin, St. Peter and Toulouse Streets. The house of Madame de Kolly which formerly was a convent, was bought by Bienville and Salmon. Half of the money of the legacy was expended for beds and the usual hospital equipment, and with the remaining 5,000 livres, a large brick hall was built.

The only description of that hospital handed down to us today is to be had from the building contract which specified:

Sieur Du Breuil promises, obligates, and binds himself to build, construct and erect on the site of the said hospital a hall measuring forty feet in length by twenty five in breadth, and fourteen in height, including the foundations, the whole in walls of well conditioned bricks, subject to the supervision to plan and payment made, which he promises to construct for the price and sum of two hundred livres per cubic fathom, full or empty and the other requisites, such as lumber planks, coverings, iron work, and entire building at the same price as those furnished to His Majesty in this country. The said work was to begin immediately for which he was to be paid on account the sum of three thousand livres in specie.

This contract was signed on the 10th day of June, 1736.

The date of the completion of that building is unknown today but it can be logically stated that

its doors were thrown open to the sick poor some time in the fall of 1736. We are told that on March 20, 1737 the hospital had five patients.

For over forty years this *Hôpital des Pauvres* was a haven of hope for and administered to the suffering of those intrepid adventurers who, drawn by the lure of a promised El Dorado and the fallacious inducements held out by the wily John Law braved privations, hardships, and the pestilences of a primeval country and became stranded on our shores.

The devastating hurricane which played havoc with the city in the summer of the year 1779 converted the Jean Louis Hospital into a heap of ruins only the kitchen and the storehouse escaped the fury of the storm. The destruction of that hospital resulted in so much consternation and suffering that in speaking of that calamity Governor Don Estavon Miros said "Many sick paupers are now wandering throughout the city in quest of shelter and succor and are hourly exposed to perish upon the very streets, or in some obscure corner.

Nothing today is known about the medical management of the Jean Louis Hospital. Apparently the professional men of that time played more than a small part in the administration of the charity of that institution. The names of the physicians who administered to those diseased unfortunates during those forty years of its existence are lost to us. There is no record that has escaped the ravages of time and no historian has perpetuated the memory of those altruistic workers in behalf of suffering humanity.

Don Andreas de Almonaster y Roxas, a peccunious old gentleman who previously had been a war clerk and a civil notary impelled by the suffering and destitution of the colonists, generously offered not only to rebuild the hospital at his own expense, but to appropriate a yearly sum for its support. He offered the magnificent amount of \$114,000.00.

In the year 1782 King Charles III of Spain gave his consent to the rebuilding of this hospital. In that same year on the same site, and with the

Charity Hospital—1815-1832

salvaged material of the destroyed hospital a commodious substantial brick edifice rose from the ruins of the original Hospital of Jean Louis. In October 1786 the rebuilt hospital then called the San Carlos (St Charles) was dedicated. The following account of that historical occasion is taken from a letter, dated January 17 1794 by Almonaster addressed to the Governor Baron de Carondelet. It reads

In October of the year 1786 when the first Mass was said and the sick were received, I was put in possession of the patronage. In conformation to the cited laws, by a solemn act, in the presence of the most distinguished persons of the City the Lord Governor Don Estaban Miro your predecessor and the vicar curate Ecclesiastical Judge Fray Antonio de Sedella, the above named gentlemen bestowed upon me in the name of the King the keys of the said Hospital which he transferred to me by the same act, so that its care may be confined to my zeal and charity

The first house physicians and surgeons of the Saint Charles hospital were Dr Don Santiago Leduc, who was appointed to the position in 1792, and Dr Don Louis Giobellina in 1794.

From an inventory made of the hospital in 1794 we learn that it had 35 small cypress bedsteads, 51 moss mattresses, 30 small linen pillows, 23 large cross-barred muslin mosquito bars, 10 small mosquito bars made of linen, 60 new sheets, 35 white woolen blankets etc. And an interesting part of this document records as the property of the hospital the following slaves. "One negro carpenter named Petro aged fifty five years, one negro carpenter named Joseph thirty five years, another Phillip sixty years old, one little negro boy named Andres of fourteen years, another

little negro boy named Francisco of two and one-half years, one negro girl named Maria, aged eleven and five lots of ground situated in the city.

This inventory not only gives us today a glimpse of the management of the hospital but reveals many interesting facts. Of special interest to us today is the Chapel. It appears that a large amount of the endowment was expended in its lavish furnishings, which were in striking contrast to the scant equipment for the use of the sick. Drugs were not listed in this document. Remedies must have been procured from the apothecaries. (There were five drug stores at that time in the city). No mention is made of surgical instruments or implements. Without doubt surgery was practiced in that institution. It must be presumed that the operations were performed in the wards on patients in their beds with instruments belonging to the attending physicians.

The census for the year 1796 gave New Orleans 9 756 inhabitants. The Saint Charles was a 24 bed hospital. Its size and capacity in relation to the then population was of more favorable comparison than the hospital of the present day. A concept of the good accomplished, the charity performed, the suffering alleviated, and the number of the sick cared for by that institution can be had only by referring to the vital statistics and the few remaining documents of that time. The extreme suffering, exposure, and the frequent pestilences to which these colonists were continually exposed, and from which only the hardi-

Charity Hospital—1832

est could escape confirmed the extremely high death rate then current. The total mortality in New Orleans in 1796 was 638, one death to every 13.57 inhabitants, making a ratio of 72.86 per thousand population.

From its foundation the hospital had derived a portion of its income from the legacies of devout and charitable persons. From the earliest time it has been the custom of the French to mention the hospital in their wills. There are scores of testaments extant in which the Charity Hospital is the beneficiary.

Don Almonaster died on the 26th of April, 1798 and he was interred in the Saint Louis Cathedral in New Orleans where his remains still repose.

The San Carlos Hospital and many other public buildings were reduced to ashes by the great conflagration which swept the city on the historical night of the 23rd of September of the year 1809.

A second time the destruction of the hospital resulted in intense suffering and hardship to the indigent sick. The rescued patients were quartered by the Mayor of the City, James Mather for but a day in the upper gallery of the Cabildo the then City Hall. Temporary quarters were then provided for the patients on the Jourdan plantation on the site of the present Industrial Canal. This most undesirable location was abandoned after six months of suffering and discomfort to the patients. For five years the Charity Hospital did not have a suitable house for the care of the sick, and it was not until the year 1814 that the square bounded by Canal Common

Phillips (now University Place) and Baronne, the present site of the Roosevelt Hotel was sold by the City to the Administrators of the Charity Hospital. The new hospital was ordered constructed by the Legislature of the State of Louisiana in a bill promulgated April 25, 1811. The corner stone of the edifice was laid in 1815.

The following description of this hospital is taken from the city directory for the year 1823:

The Charity Hospital, situated N. 147 Canal Street, consists of two large buildings, containing one surgical hall, two large fever wards, one dysentery ward, one ward for chronic cases, one for females, one for convalescents, one building room, one apothecary store and a number of other apartments for the families of the residents, officers, etc. The Hospital has lately undergone a complete repair and reform, and is at this time as clean, wholesome, and well conducted as any institution of the kind in the Union. During the last year about 700 sick persons were admitted, 1200 of whom were discharged well, and the remainder died, one-half of which, of Yellow Fever. The lot on which these buildings stand embraces the whole square between Canal, Common, Baronne and Phillips streets, and is laid off as a garden and poultry yard, etc. About 1200 males and females were admitted during the year '82, and as many as 120 persons received attention at one time.

It was a 120 bed hospital. This institution in its equipment and management was second to no other in this country. There were bathing facilities, an apothecary and the fever cases were segregated from surgical cases.

In 1820, an Act of the Legislature provided for the erection of a separate building "to receive and attend such persons as may have fallen into a state of insanity."

Because the rapidly growing population of the city and the extraordinary number of destitute sick from every state of the Union and from every country of the world demanded a larger and more commodious institution, the State Legislature in 1830, authorized the selling of the hospital building on Canal street. In 1832 it was sold to the State for \$125,000.00. The main building was then converted into the Capitol of the State of Louisiana. Years afterward the Common street side of the square became the site of the Medical College of Louisiana, now Tulane University.

The present site of the Charity Hospital was selected in 1832. The cost of construction and of the grounds amounted to approximately \$150,000.00. The magnificent edifice, the main building of the splendid group of buildings which today comprises the Charity Hospital of Louisiana, and which has reached its centenary, stands today practically the same as on the first day it opened its doors and inaugurated its long service to suffering humanity. Even now it stands as a model of hospital architecture for this climate: its high ceilings, its long and wide halls, its numerous large outside openings and its spacious verandas give it sufficient ventilation, make it cool in summer and at all times cheerful. These are features of construction not usually found in modern institutions.

The following description of the so called New Charity Hospital was published in New Orleans in 1840:

The building was of great size, being about 300 feet in its total length, and three stories high. It is composed of a corps of loges opening into a spacious hall, intersected at right angles by another running lengthwise of the building on which the wards open. From this hall access is had by broad stairs to the upper stories which are similarly divided, and thus to the cupola from which there is a magnificent view of the city and environs. The lower story is occupied by the Library, Physicians' Room, Surgeons' Room, etc. and the second and third stories into wards for the patients, twenty-one in number, as also into four other apartments designed as such. It is calculated to hold 540 patients.

The second floor was appropriated to the use of female patients and was divided as follows: A ward for women of good character, another for those of bad, and also one for the exclusive use of surgical and obstetrical cases. The grounds around it were enclosed with a substantial brick wall, and were handsomely improved and neatly kept.

The portals of this edifice were thrown open to the destitute sick on October 8, 1832.

The Sisters of Charity inaugurated their long period of admirable devotion to the sick and afflicted on January 6, 1834. For over a century they have given uninterrupted altruistic services to the Charity Hospital. Too much cannot be

said in praise of these pious religious, who spurning all mundane glory, dedicated their lives to unrelenting toil for the alleviation of suffering, and who have braved pestilences and epidemics and even risked existence itself for the devoted love of humanity. The services of the Sisters of Charity are indispensable to the Charity Hospital and their value cannot be appraised merely in monetary terms. The respect they command is an incentive to a greater discipline and a stimulus to more energetic work from their subordinates. In actual work, in enforcing economy in preventing waste, their services have been invaluable and their scrupulous management of the domestic and nursing departments has been the leading constituent in the success of the institution through a century of uncertain revenues and inadequate appropriations.

In the past hundred years the growth of the Charity Hospital was rapid. In the 1840's its yearly total number of admissions was from eleven to sixteen thousand patients. It was then one of the largest if not the largest hospital in existence.

Today the Charity Hospital has a capacity of 1,765 beds. The total number of indoor patients for 1931 was 47,182, with a daily average of 2,102. Its outdoor clinics numbered 318,735 consultations. Its records for that year give 26,124 operations including those performed on the eye, ear, nose and throat, and 2,566 obstetrical cases.

A magnificent seven story edifice with a capacity of 250 beds for the convalescents has been constructed.

More than one-third of the deaths registered in New Orleans occur in that institution. Approximately only one half of the total number of indoor patients are residents of New Orleans; the remainder is composed of individuals from every parish of Louisiana and from every neighboring state. Naturally this unusual condition results in an excessively large non resident mortality in that city and a corresponding inflation of its death rate. This condition is unique among the large medical centers of this country.

For 100 years this institution has been the cradle of medical education in the South.

From an historical standpoint as well as from the unlimited scope of its charity it stands unique among the great hospitals of the world. It was founded nearly two hundred years ago during the time of the French domination. It was rebuilt with the sanction of the King of Spain, when Louisiana was a Spanish possession. In the early period of the nineteenth century, its history emblazons in immortal pages an epic of

the greatest distress and suffering ever experienced by man. During the trying days of the Civil War it was converted into a military hospital for the care of the Union soldiers.

In the beginning of the past century when New Orleans was in the making when it was a city to which unknown thousands of young pioneers, the flower of manhood from every state of the Union and from every country of the world, flocked in quest of wealth or of refuge from political despotism and religious persecution, unfortunately too

often to have their hopes and ambitions shattered, to become a prey to the ever recurrent epidemics or to prematurely fill a wet grave the Charity Hospital was their only haven in their dire hours of suffering and despair.

Then it was not the Charity Hospital of Louisiana, but the Charity Hospital of the World. Well may it be said of this institution:

The deeds of charity we have done stay with us forever. Only the wealth we so bestowed do we keep. The other is not ours.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE little book by Clapp on cataract is a timely and useful one, since there had not appeared in English any summary of the recent important advances in our knowledge of the crystalline lens comparable to the book of Siegrist or chapters of Jesse and Hess in the larger German handbooks.

The chapters contributed by Ida Mann on the embryology and comparative anatomy of the lens are excellent for the amount of space given them and are especially important for the study of this fascinating organ whose entire history from the closing of the lens vesicle to adult life is now made visible to the clinician by the slit lamp and corneal microscope. Knowledge of this history allows proper interpretation of the various forms of congenital lens opacity and their distinction from acquired or senile opacities which are progressive. The more important of these congenital forms are described and illustrated, in some instances by good original drawings from the Wilmer Institute. In most cases, illustrations have been carefully selected from the previous literature.

A chapter on the chemistry of the normal and pathological lens shows a thorough knowledge of recent important work, including the demonstration of true oxygen metabolism in the avascular lens and of the presence of glutathione as the important hydrogen donor in this process. This substance is absent in the completely cataractous lens, and this fact is possibly of importance in the genesis of cataract. In spite of the great amount of chemical investigation and a knowledge of the etiology of certain types of cataract such as that after removal of the parathyroids no generally accepted theory as to the etiology of senile cataract has been formulated. The author's own investigation of the growth of the lens and its increase in weight from the seventh to the one hundred and fiftieth day is interesting.

In discussing the various types of acquired cataract and their treatment the author includes a great number of references to the literature, but at times has apparently not fully digested this work, since work of little importance is given equal space with that of real value. Thus it was hardly necessary to mention the injection of nitrogen into the anterior chamber to prevent traumatic cataract, a procedure purely experimental and clinically untried while the brief assembly of positive and negative evidence as to the occurrence of cataract in leprosy

leaves us practically where we started. The classification of senile cataract is not very clear since surely peripheral cataracts and cortical opacities are one and the same, while morgagnian cataract is definitely a subdivision of hypermature cataract.

The non-surgical treatment of cataract is discussed, as it should be, without enthusiasm though perhaps the author's negative conclusions might be even more strongly stated.

The discussion of the various types of cataract operation, anesthesia, paralysis of the lids before operation (akinesia) and after-care, is excellent. In discussing Verhoeff's method of intracapsular extraction no mention is made of an important change in his technique by which the lens capsule is grasped at the upper equator instead of below. In Sinclair's method, the important fact that his capsule forceps are made with a cross-action handle and hence retain their hold on the capsule automatically is omitted. It seems to the reviewer that among the methods of operating for glaucoma following cataract extraction, cyclo-dialysis, which is employed as the operation of choice by Elschnig and others for this condition, should have been included.

The discussion of the complications of the cataract and their treatment is quite complete. It is only natural that the theory of anaphylactic reaction to lens protein as an explanation of reactions following retention of cortex should be accepted by the author on account of the work of his associates, although many authorities differ with him on this point. The full bibliographies offer an excellent opportunity to those interested in further study of particular questions which arise, altogether the book is well adapted to stimulate such study.

SAMFORD R. GIFFORD

THE appearance of the second edition of *Practical Obstetrics* by Bland and Montgomery within 2 years is proof of the popularity of the first edition. The present edition is an improvement over its predecessor but a few points of difference may be noted between the authors and the reviewer. In the differential diagnosis between simple vomiting of pregnancy and pernicious vomiting, the authors say (p. 159) that the "neurotic element (is) lacking in the latter. This statement is at variance with the opinion of many obstetricians. In the discussion of

PRACTICAL OBSTETRICS FOR STUDENTS AND PRACTITIONERS. By F. Brooks Bland, M.D., and Thaddeus L. Montgomery, M.D. 2d ed. Philadelphia: F. A. Davis Co. 1934.

pages and 400 illustrations. The work is replete with case reports illustrated by slides, photographs, and roentgenograms. The remainder of the text is concerned with pathogenesis, microscopic and roentgen findings, rather than clinical diagnosis and prognosis. Practically nothing is given on clinical treatment except in case reports.

Malformations, fractures, and inflammation of the jaws are treated adequately and endocrine and

nutritional disturbances are each given a chapter. At least two-thirds of the book is allotted to cysts and tumors which are discussed exhaustively and very lucidly. The thoroughness of preparation is suggested in the unnecessarily complete bibliography which is appended to each chapter.

This book is scarcely styled for a textbook but as a reference work it will be a distinct addition to the literature of the subject. CHARLES W. FREEDMAN

HYPERPARATHYROIDISM

CLINICAL DIAGNOSIS AND THE OPERATIVE TECHNIQUE OF PARATHYROIDECTOMY

FRANK H. LAHEY, M.D., F.A.C.S. AND G. E. HAGGART, M.D., F.A.C.S., BOSTON, MASSACHUSETTS

THE clinical syndrome—hyperparathyroidism—due to excessive parathyroid secretion as occurs with adenoma of the parathyroid gland is now a well established entity. Rapid and pronounced relief of symptoms follows removal of the parathyroid adenoma. The differential diagnosis, however, is often confusing so that a true case of hyperparathyroidism may be missed or may even be unsuspected. The location and removal of the adenoma may present serious technical difficulties as evidenced by reports in the literature of cases operated upon several times in an attempt to find the adenoma.

In this paper five new proved cases of hyperparathyroidism are briefly reported and the significant findings which led to the diagnosis are discussed. The operative exposure for removal of a parathyroid adenoma is illustrated with particular emphasis upon the possible atypical location of parathyroid bodies—and so these tumors.

A consideration of the historical background of hyperparathyroidism is not included in this paper. (For references in this connection see bibliography.) It is however of interest to note a recent report by J. Bauer on further developments in the patient upon whom F. Mandl in 1926 performed the first operation to remove an adenoma of the parathyroid for relief of osteitis fibrosa cystica. Bauer reports as in the original articles by Mandl

that the initial result was good and a formerly bedridden patient was able to walk without pain at the end of 2 months. This improvement lasted for 6 years. In 1932, however, this patient was admitted to Bauer's clinic because of a return of the original symptoms of pain on movement of the extremities and because of progressive deformity of the skeleton. During hospitalization the patient developed renal colic caused by calculi. There was a hypercalcaemia (blood calcium 12.5 milligrams per hundred cubic centimeters) while the phosphorus was low (2.5 milligrams per hundred cubic centimeters). There was a negative calcium balance due to excretion of a large amount of calcium in the urine. A second operation was undertaken by Mandl because there appeared to be a return of the state of hyperparathyroidism. No tumor, however, was found. A subtotal thyroidectomy was therefore done. In this tissue Professor Sternberg found one normal parathyroid on the surface of and another within the body of the thyroid gland. There was no improvement following the operation. Bauer felt that symptoms persisted because of a hyperfunctioning adenoma of the parathyroid which because of inaccessible location was not found.

In view of the experience just related, as well as from a perusal of other cases reported in the literature together with our own experience

rience it is obvious that pronounced technical difficulties are frequently encountered in attempts to locate and remove adenomata of the parathyroid gland

Paget's disease of bones and parathyroid tumor In view of this recent report on the further progress of Mandl's case Kienbock states that a consideration of the entire course of this patient convinces him that the original diagnosis of Recklinghausen's osteitis fibrosa was erroneous. He believes this patient to be a case of Paget's disease of the bones associated with the unusual complication of a parathyroid tumor with the bone changes as described which in turn are rarely observed in Paget's osteitis. Emphasis is placed upon the absence of large cysts as seen in Recklinghausen's disease. Kienbock believes that the occurrence of the parathyroid adenoma in this instance was a coincidence rather than a cause of the condition. He further states that the mild form of hyperparathyroidism as suggested by the studies of the blood chemistry in Mandl's case is not infrequently seen in the porotic form of Paget's disease. Kienbock feels, however, that the two conditions, hyperparathyroidism and Paget's osteitis, are definitely distinct clinical entities. This conclusion is also stressed by W. Bauer. The authors in 5 cases of Paget's disease, have at no time found reason to suspect the presence of a parathyroid adenoma because the clinical data are not similar to that found in hyperparathyroidism. X-rays do not reveal a generalized skeletal involvement. Clinically Paget's disease of the bone is a different picture from that presented by hyperparathyroidism.

Chronic rheumatoid arthritis and hyperparathyroidism It has been suggested that hyperparathyroidism is an etiological factor in the ankylosing type of chronic arthritis. One of us (GEH) reviewed the findings in 200 carefully studied cases of chronic rheumatoid arthritis. In no instance was the diagnosis of hyperparathyroidism confirmed. For example, the blood serum calcium and phosphorus estimations were consistently within normal range while roentgenograms of the skeleton did not reveal the characteristic X-ray findings as described below.

DIAGNOSIS

The diagnosis of the clinical entity hyperparathyroidism depends primarily upon (1) an analysis of the chemical findings and (2) a careful survey of the roentgenograms, including not only those of the bones of the skeleton (especially plates of the skull spine, pelvis and femora) but also X-rays of the kidneys. The latter plates are taken to demonstrate the presence or absence of calculi. In very early cases of hyperparathyroidism or in the presence of severe renal damage study of the chemistry and X-ray findings may be misleading and the diagnosis not arrived at.

From the clinical standpoint cases of hyperparathyroidism may be conveniently classified in one of the following three groups:

1. Classical—the osteitis fibrosa cystica of von Recklinghausen's. Skeletal roentgenograms of these patients are quite characteristic, showing not only the diffuse granular osteoporosis but also the presence of multiple cysts.

2. Hyperparathyroidism with osteoporosis—these cases are an early stage of group one and rarely show cyst formation. The decalcification of the bone is not as advanced as in group one but there is present the characteristic osteoporosis, although at an early stage, as described below.

3. Cases in which renal pathology due to the precipitation of calcium phosphate, is the significant finding. In these patients X-rays of the skeleton are often negative. Albright, Baird, Cope, and Bloomberg have subdivided this group of cases as follows:

- a. Calculi in the renal pelvis, with resulting pyelonephritis. In a review of 38 cases there were 27 per cent in this group.

- b. Calculi in the renal tubules, with resulting renal sclerosis, contraction and insufficiency (23 per cent).

- c. Precipitation of calcium phosphate in the kidney as one of several organs with acute renal failure and death of undetermined cause in a few hours or days (1 per cent).

It is important to realize that renal lesions may occur without evidence of changes in the skeleton. The former are an index of the severity of the disease and the latter an index to its duration.

Fig. 1 On these diagrammatic illustrations of the anterior aspect of the thyroid we have recorded the locations at which we have encountered parathyroids in the course of several thousand thyroid operations and the points where we have discovered bodies suspected and proved in 190 cases by microscopic section to be parathyroid bodies. These are the cases in which we have searched thyroid specimens while still sterile, in which we have found and transplanted microscopically proved parathyroids. Of all these locations, that representing the superior parathyroid by dotted lines in 7 as being on the back of the upper pole where it rests against the larynx has been the most constant. The intrathyroid parathyroid as shown by barred lines in 8 is the location at which we have found parathyroid adenomata twice. Note in 7 a parathyroid shown in dotted lines on the posterior aspect of the thyroid resting against the trachea at the point where the isthmus and body join. Note in 14 the mediastinal location of a parathyroid and in 9, 10 and 12 parathyroids on the anterior aspect of the gland.

CLINICAL ASPECTS OF HYPERPARATHYROIDISM

The majority of the reported cases have occurred in females between 30 and 50 years of age. From an analysis of 115 proved cases (as detailed in the literature) Gutman, Swenson and Parsons state that pain in the back or extremities was the major initial symptom in 72 per cent, while 22 per cent primarily complained of muscle weakness. The possibility of hyperparathyroidism must always be considered in patients who complain of relatively diffuse 'neuritic' or 'arthritic' pains made worse by motion. This is particularly

Fig. 2 These diagrammatic illustrations represent the thyroid gland pulled inward and exposing its entire posterior aspect as shown in the surgical illustrations Figures 9, 14, 19, 26, to 30 demonstrating the location of parathyroid adenomata at operation. On these are placed the locations at which inferior parathyroids have been demonstrated at thyroid operations and found and proved by microscopic section on the 190 parathyroid specimens removed and proved at the operating table. The most constant locations of parathyroid glands have been as shown in 3, 4, 5 and 6.

true if the symptoms exhibit localized or general bone tenderness and if there is a history of pathological fracture. Not infrequently patients will report a progressive loss in stature (see Case 4).

The majority of the cases in the literature were reported to be in negative calcium balance. That is these patients required a larger amount of calcium than the amount ordinarily believed to be adequate for maintenance of the normal individual in equilibrium. In early states of the disease a negative balance may not be present while in patients with bone involvement from multiple myeloma or metastatic carcinoma a definite negative calcium balance can often be demonstrated.

Classical hyperparathyroidism is characterized by an increased ratio of calcium in the urine to the total amount of calcium excreted

FIG 3

FIG 4

FIG 5

FIGS 3, 4, and 5. Case. Photographs of patient with hyperparathyroidism showing marked deformity of spine and thorax. Compare with Figures 7 and 8.

except in group 3 cases where the renal function is seriously impaired.

Blood chemistry. Classical hyperparathyroidism usually reveals an elevated blood calcium and relatively low phosphorus. The blood phosphatase activity is also increased. Taking the serum calcium value of 11.5

milligrams as a high normal Gutman reviewed 78 cases in which the determination was recorded and found a blood calcium above 12 milligrams in 59 cases, while serum inorganic phosphorus determinations below 2.5 milligrams were found in 26 of 52 cases.

Obviously hypercalcemia and hypophosphatemia are not consistently found in suspected cases. Particularly is this true in the presence of severe renal damage. Albright has shown that in these cases (group 3) the blood serum phosphorus rises, and the calcium tends to fall. Furthermore, Peters and Van Slyke have stressed the necessity of interpreting serum calcium values in view of the phosphorus and blood serum protein determinations.

In reviewing our knowledge of the blood phosphatase Kay states it to be an enzyme present in the calcifying cartilage and that its rise in hyperparathyroidism is a secondary effect. The source of the increased amount of blood phosphatase is not definitely known. Albright and his coworkers feel that this determination is an index of the degree of bone involvement, because in clinically proved cases of early parathyroid disease, without demonstrable bone change, the blood serum phosphatase is normal (normal being approximately three Bodansky units). Very high values have been found in active rickets (thirty to one hundred and sixty-five units) and in generalized Paget's osteitis (fifty to one hundred and thirty-five units). The same is

FIG 6. Case. Roentgenogram of skull showing thickening of calvarium with loss of clear demarcation between the inner and outer table. The diffuse osteoporosis is well shown.

Fig 7 Case 1 Anterior posterior roentgenogram of thorax illustrating deforming action of muscles of respiration on the softened bone

Fig 8 Case 1 Lateral roentgenogram of spine exhibiting pronounced crushing down of vertebral bodies with consequent loss in stature

true in the blood serum of patients with obstructive jaundice

X ray findings If the diagnosis of hyperparathyroidism is suspected X ray studies should include plates of the skull spine and pelvis. In addition to roentgenograms made of the extremities presenting symptoms plates of the femora and humeri are also helpful in detecting early bone change. The characteristic changes in the skeleton together with comparable pathological findings as described by Hoffmeiz are outlined as follows

Skull (Figs 24-27) There is a definite thickening of the calvarium together with a pronounced blurring of outline so that the demarcation between inner and outer tables is very poorly defined at times lost. The bones present a finely mottled granular appearance that is a diffuse osteoporosis. In the more advanced cases there are large irregular areas of diminished density and these are often more pronounced in the mandible and maxilla.

From observations at necropsy Hoffmeiz found the surface of the bones of the skull to be very rough with numerous irregularly spaced sharp pointed projections between which were depressions averaging 2 to 3 milli-

imeters in size. Also seen on the bone surface were scattered depressed areas 2 to 3 centimeters in diameter with adjacent osteophytic deposits. Most of the bone was sufficiently soft to be easily cut with a knife. The inner and outer tables could not be recognized on section.

In a chemical analysis of bone from a patient with hyperparathyroidism Wilder found considerable loss of calcium and phosphorus and a relative if not an absolute gain in organic matter.

Vertebrae The vertebral body of advanced cases shows a pronounced crushing or narrowing particularly at the anterior margin (Fig 8). In less severely affected vertebrae there is an increase in the convexity of the superior and inferior body surfaces. Such deformity affecting many vertebral segments results in a pronounced kyphosis thus causing a marked increase in the normal anterior posterior curve of the spine, as well as a loss in stature (Fig 8). The vertebral body in some instances presents a finely mottled appearance with coarse perpendicular striae. In other cases (Fig 29) there is a diffuse, rather even,

Fig 9. Case. In this drawing made by the artist at the operation, the top of the large intrathoracic parathyroid adenoma may be seen appearing just above the level of the clavicle and the size of the intrathoracic portion outlined by dashes upon the chest wall. The shadow of this intrathoracic parathyroid tumor is demonstrated in the accompanying X ray film of this patient's superior mediastinum. Note the high position of the inferior thyroid artery. We have called attention to the not infrequent high course of this vessel. The recurrent laryngeal nerve was safely located as it so often is in intrathoracic thyroid adenomata posterior to the intrathoracic parathyroid adenoma so that it was not injured.

decalcification of the entire bone. The intervertebral discs are not affected.

In connection with the spine Figure 7 well illustrates the deforming action of the muscles of respiration on the softened thoracic cage, a deformity analogous to that seen in severe rickets.

Pelvis. The pelvic bones exhibit changes similar to those seen in the skull. In many instances, the pelvis is markedly deformed, presenting a wedge-shaped appearance with large cystic areas scattered throughout the bone.

Bones of the extremities. Figure 12 shows the femora of Case 2 upon which X ray films the diagnosis of hyperparathyroidism

was made to be later confirmed by chemical analyses and operative findings. These plates are typical of the early bone change (type 1) and illustrate a slight but definite diffuse osteoporosis of the femora.

Compare the plates mentioned with those of Figure 18 which illustrates bone change in the femur of an advanced case of hyperparathyroidism of long duration. Here is seen evidence of old healed spontaneous fractures. The cortex of the bone is exceedingly thin. There is a pronounced generalized demineralization so marked indeed that the mottled appearance is not evident. Where cysts are found expansion of the cortex occurs. There is no periosteal proliferation.

The characteristic subperiosteal rarefaction of the cortex and the formation of small cysts are usually best shown at the metaphysis of the long bones and on the superior and inferior margins of the ribs.

The pathological studies of Hoffmann reveal that the bones of the extremities show much less evidence of alteration of structure than is the case in the bones of the skull. In the femora and humeri even in advanced cases, there is a clear differentiation between the cortex and the spongy bone.

Location of bone changes. The site of the bone lesions in hyperparathyroidism may be explained by the work of Jaffe, Bodansky and Blair through their investigations on guinea pigs, dogs, and rats. These animals were given large doses of parathormone with the resulting specific effect of decalcification of the bones. The resorption of bone was established by histological study which revealed the presence of large haversian canals and of lacunae containing osteoclasts on the periosteal and endosteal surfaces of bone.

The authors point out that bone resorption and bone deposition is a process that constantly goes on in all bone and that these processes are more rapid in the regions of active bone growth. If the rate of either resorption or deposition of bone is increased it is increased throughout the animal body. Hence, if a condition is present favoring an excess of resorption of bone, as hyperparathyroidism, such resorption will be most evident in the regions of active bone growth. A pronounced

Fig 10 Case 1 Photograph of tumor removed

stimulus as hyperparathyroidism of long duration would be necessary to affect the whole skeleton

The above theory would then explain the pronounced susceptibility to resorption of the spongy bone of the metaphyses and of the cortical shaft in the epiphyseal regions in the rapidly growing long tubular bones as well as resorption at the costochondral junctions of the ribs the rib cortex and in the bones of the skull

Summary of X ray findings The bone changes in hyperparathyroidism as shown by roentgenograms may therefore be summarized as follows

1 In the relatively early cases there is a diffuse osteoporosis The bone exhibits a finely mottled granular appearance or there may be a pronounced general demineralization of the bone. In the more advanced cases there are large irregular areas of diminished density with cyst formation The cortex of the long tubular bones is exceedingly thin particularly in the epiphyseal regions. No periosteal reaction is seen

2 In long standing cases bone deformity is present viz a pronounced kyphosis of the spine due to crushing down at the anterior margin of many vertebral bodies, deformity of the ribs the result of action of muscles of respiration on the softened thoracic cage wedge-shaped pelvis and finally the de-

Fig 11 Case 1 Photomicrograph of parathyroid adenoma $\times 475$

formities following spontaneous fracture of the long bones.

With the diagnosis of hyperparathyroidism established the problem then relates itself for the most part to the question of finding the parathyroid adenoma and removing it. Albright Bauer and Churchill have recently reported cases of hyperparathyroidism apparently not due to adenomata of the parathyroids but rather to hyperplasia of all the parathyroids This finding as we have previously stated complicates the management of hyperparathyroidism and if proved by further experience with this condition to be convincingly true may explain some of the cases in which search for a parathyroid tumor has proved unsuccessful

Failure to find parathyroid adenomata in many cases will be due to failure to realize the frequent atypical location of the parathyroids and failure to investigate the possible atypical locations for a possible parathyroid adenoma

It becomes also the duty of pathologists in view of this report from a group of men who have done such sound work in connection with this disease to familiarize themselves with the normal and abnormal pathology of the parathyroid gland, since it will be necessary in cases in which adenomata cannot be found to call the pathologists into the operating room for opinions on frozen sections first as to whether removed specimens are, or

Fig. 12 Case 2. Note the slight but definite diffuse osteoporosis of these femora. (Type 2)

Fig. 13 Case 2. Anterior-posterior X-ray picture of cervical spine which show early even generalized demineralization of the bones to be compared with Figure 12. In this plate definite hypertrophic arthritic changes are also seen. The one patient in this series in which these findings were observed.

are not parathyroids and second whether or not parathyroid hyperplasia if adenomata are not found comparable with that in hyperthyroidism exists and whether or not on such evidence combined with the clinical findings subtotal parathyroidectomy is justified. With these ideas in mind our pathologists have undertaken a review of the histology of all of our fixed and preserved parathyroid specimens amounting to one hundred and ninety specimens, each representing a section of an individual parathyroid—their report to be published later.

As the result of the plan which we have published previously¹ of searching every thyroid specimen surgically removed for possible parathyroids and of reimplanting the removed parathyroid body into the left sternomastoid muscle, a large number of parathyroid glands have been found on the removed thyroid gland. Due also to the policy before transplantation of cutting off a small gross section of the suspected parathyroid gland and submitting it to the pathologist for

report we have acquired a relatively large mass of parathyroid material and a microscopically proved experience in deciding as to what is and what is not a parathyroid, with variation in shape, size, color and location of these glands.

The parathyroid most easy to distinguish has a brownish color varying from dark to light mahogany brown. It has molded edges, quite similar to the molded edges seen in a miniature lima bean. In fact one of us (FHL) has often stated that, except for the fact that they are small and tend to be convex on one side and concave on the side in contact with the thyroid the typical non adenomatous parathyroid more closely resembles a miniature lima bean (except as to color) than any thing else.

As the result of our experience now with over 13,000 thyroid operations in all of which the regions where parathyroids are found are widely exposed and when possible parathyroids demonstrated, we have learned that there is considerable variation in size in the non-adenomatous parathyroid glands from that of the head of a match up to the size of a small lima bean. We have likewise learned

Frank H. Labey: The translocation of parathyroids in partial thyroidectomy. *Surg. Gynec. & Obst.* 1930, 41: 266-269.

Fig. 14. Case 2. The parathyroid adenoma as shown in this illustration made at the time of operation was found in the groove between the trachea and esophagus behind the trunk of the inferior thyroid artery and beneath the recurrent laryngeal nerve. This is not an uncommon location for parathyroids. As may be seen in the diagrammatic illustrations, Figures 1 and 2 showing the points on the back of the thyroid gland where parathyroids have been found in thyroid operations, should an adenoma occur in the parathyroid shown in Figures 3, 6 or 7 it would be located in just the same position as was the one in this case. The tumor shown in the jaws of the hemostat is the actual size of the parathyroid adenoma on removal.

The course and relationship of the inferior thyroid artery and recurrent laryngeal nerve as shown here is the one which we most commonly see in our thyroid operations.

Note in all of these cases that the prethyroid muscles have been cut, the gland pulled inward with thyroid grasping forceps, and its posterior aspect widely exposed.

that the back of the thyroid gland (in contact with which gland the parathyroid glands commonly rest) is sometimes quite free from yellow fatty tissue so that brown parathyroids are readily located and distinguished while at other times this region is thickly sprinkled with fat particularly about the point where the branches of the inferior thyroid artery penetrate the gland and where inferior parathyroid glands are so often demonstrable thus making the demonstration of these bodies less certain.

Such parathyroids are sometimes overlaid by adipose tissue and are yellow or pale white in color. In such fat infiltrated parathyroids one of us (FHL) has noted the tendency of these glands to be more globular in shape and to have lost the molded edges characterizing the more typical more easily distinguished glands.

Fig. 15. Case 2. Photomicrograph of parathyroid tumor tissue $\times 140$.

Early in our experience with parathyroid bodies we had impressed upon us and remarked it in our publications on this subject that these glands were often atypically located and that they might be found anywhere—on in behind or below the thyroid gland. During one of his visits with us Dr. Wallace I. Terry became interested in our demonstration of atypically placed parathyroids and delegated one of his junior men, Dr. Raymond J. Millner, to search all specimens for such atypically located parathyroid glands with the result that valuable reports concerning such atypical locations have also emanated from Dr. Terry's clinic in San Francisco. Recently with the interest intensified in hyperparathyroidism reports are frequently appearing in this country and abroad concerning atypically located parathyroid bodies which have become the site of parathyroid adenomata.

The two most constant points at which we have found parathyroid bodies have been on the back of the gland close to the point at which the inferior thyroid artery enters the gland and below the lateral exit of the middle and lower thyroid veins (the inferior parathyroids), and on the posterior lateral aspect of the upper pole of the thyroid where it rests against the laryngeal cartilage (superior parathyroid).

We have seen microscopically proved parathyroid bodies atypically situated so often in

Fig 16

Fig 17

Fig 18

Fig 16 Case 3. Roentgenogram of lower spine and pelvis. A long standing case of hyperparathyroidism with consequent bone deformity. Compare with Figures 17, 18.

Fig 17 Case 3. Lateral X-ray film of lower spine illustrating marked crushing down of vertebral bodies with old healed fracture.

Fig 18 Case 3. Compare with Figure 17. Here are shown the bone changes in the femur of an advanced case of hyperparathyroidism of long duration. The old but now healed spontaneous fractures are evident. The cortex of the bone is exceedingly thin. Generalized demineralization is seen. There is no periosteal proliferation.

a variety of locations that it has seemed best to illustrate their possible location by placing them on diagrammatic outlines of the thyroid seen from an anterior (Figure 1) and posterior (Figure 2) view. We have seen parathyroids in the mediastinum (parathyroid adenomata and on intrathoracic goiters) on the side of the thyroid gland, on the front of the thyroid gland, in the bundle of vessels entering the upper pole, in the groove between the trachea and esophagus well away from the gland, out on the trunk of the inferior thyroid artery, before it had divided and within the substance of the thyroid gland itself. Dr. R. B. Cattell, working in the Clinic in 1924 on the relation of the histology of the thyroid to the administration of iodine (at which time sections were made of 400 hyperplastic thyroid glands removed at operation) first called our attention to the relative frequency with which intrathyroid parathyroids were found within the specimen removed by subtotal thyroidectomy.

As the result of a large experience (190) with the microscopically proved parathyroids at thyroid operations and on the specimen immediately after the operation with the specimen still sterile, we believe we can safely state that a parathyroid may be found at practically any position on in, behind, or below the thyroid gland.

The technique of demonstrating and removing parathyroid adenomata is related largely to exposure of the region where parathyroid bodies are found when typically located and a knowledge of the regions in which to search for them when parathyroid adenomata are not demonstrated in typical locations.

The first requirement of any operation for removal of a parathyroid adenoma is exposure. This involves in our hands an adequate thyroid incision with a severing of the prethyroid muscles high between clamps. Without these muscles severed we are not able to obtain wide exposure of the back of the gland from its lowest point up to its upper pole.

Fig. 19. Case 3. In this illustration made at the time of operation one sees the upper pole of the thyroid gland split where it rests against the larynx and an intrathyroid parathyroid demonstrated within the substance of the thyroid gland. By pressing the upper pole of the thyroid gland against the thyroid cartilage, this small tumor could be palpated as a bean-like structure within the gland, demonstrated removed and immediately proved by frozen section to be a parathyroid adenoma.

As stated in the text, in a case seen in consultation, see Figure 32 a and b, in which two previous unsuccessful searches for a parathyroid adenoma had been made, at our suggestion a careful search at the third operation for an intrathyroid parathyroid revealed one and permitted its removal. Where definite chemical, clinical, and X-ray evidence of hyperparathyroidism are present but the parathyroid tumor not evident on operative exposure, careful palpation of the thyroid gland must be made with the possibility that the parathyroid adenoma is within the gland.

In the diagrammatic drawing (Fig. 1) showing the locations of parathyroids from the front of the gland, this position is shown in 8. This should not be a very uncommon location for parathyroid adenomata since 7 shows in dotted lines the location in our experience of the most constantly placed superior parathyroid just behind the internal and lateral aspect of the upper pole where it rests against the thyroid cartilage.

With the muscles severed the middle thy thyroid veins are ligated between clamps so that the lateral vascular attachments of the thyroid to the internal jugular vein are severed. The outer border of the thyroid gland is then grasped with the thyroid grasping forceps

Fig. 20. Case 3. Photomicrograph of parathyroid adenoma from this patient X500

which we have described lifted up, and rotated inward. The internal jugular vein and common carotid artery are completely separated from the back of the thyroid gland and the inferior thyroid artery completely demonstrated as a trunk where it passes behind the common carotid artery. The back of the gland is inspected for a tumor body on the gland and if a tumor cannot be seen, it is palpated for such a tumor within the gland. An adenoma of a parathyroid usually converts that structure into a globular mass and changes its color to a pale white rather than the brownish color characterizing the typical normal parathyroid.

Parathyroids involved or uninvolved by adenomata are characterized by being so movable on the back of the thyroid that they are demonstrably not part of that gland. On removal they have a glistening covering entirely surrounding the removed structure with no area over which this shining covering is absent. This is of value in distinguishing a parathyroid adenoma from an extruded adenomatous thyroid area in that the latter structure is usually connected with the thyroid itself by an isthmus of thyroid tissue, the severing of which in its detachment from the thyroid leaves a cut surface of thyroid tissue—interrupting thus the smooth and complete glistening capsule which is to be found in both parathyroids and parathyroid adenomata.

Fig 21

Fig 21. Case 4. Photograph of patient illustrates the upper dorsal round back, with consequent loss of stature due to crushing down of vertebral bodies as illustrated in roentgenograms of the spine, see Figures 22 and 23.

Fig 22

Fig 23

Figs 22 and 23. Case 4. Anteroposterior and lateral roentgenograms of spine. The body of the fifth dorsal vertebra is represented only by a thin wedge of bone. The patient stated there has been progressive loss in height.

Should no parathyroid adenoma be demonstrable on this exposure the inferior thyroid artery must be completely dissected up to its entrance into the thyroid gland. The recurrent laryngeal nerve must be found and dissected up to its passage behind or in front of the inferior thyroid artery. We have found and removed a parathyroid adenoma at this point behind the recurrent laryngeal nerve and inferior thyroid artery (Fig 14).

If still no parathyroid adenoma is found, one must expose the groove between the trachea and esophagus in the region of the inferior thyroid artery. If still the adenoma is undemonstrated the superior thyroid artery should be ligated and the upper pole of the thyroid turned downward so that the region where it rests against the thyroid cartilage may be inspected. In dissections at this point troublesome bleeding may arise from the ascending branch of the inferior thyroid artery a branch of which usually nourishes

the upper parathyroid. In controlling bleeding at this point caution must be exercised as the recurrent laryngeal nerve enters the larynx here, at the point where the lowest fibers of the inferior constriction are inserted into the horn of the thyroid cartilage shown at X in Figure 26.

In the event that the tumor is still not found one palpates the thyroid through and through between the thumb and the forefinger and any discrete globular nodule within the gland is exposed by an incision into the gland removed and submitted to the pathologist for immediate frozen section report as to a possible intrathyroid parathyroid. We have removed such an intrathyroid parathyroid as shown in Figure 19.

The X ray picture of the bones of another patient is shown in Figure 35 a and b demonstrating to what an extreme state decalcification can extend in hyperparathyroidism. This patient was seen in consultation with Dr

Fig. 24. Case 4. The generalized decalcification and soft mottled appearance of the skull is characteristic.

Fig. 25. Case 4. Roentgenogram of pelvis illustrating the multiple large cystic areas seen in these bones.

Robert C. Cochrane at the Boston City Hospital. She was a case of proved hyperparathyroidism and had previously had two normal parathyroids removed without relief of symptoms. We advised another operation and a search within the thyroid gland itself. Such a search revealed an intrathyroid parathyroid adenoma which was removed.

With failure still to demonstrate the parathyroid tumor, the search is continued in the bundles of the superior thyroid vessels out along the main trunk of the inferior thyroid artery, behind the oesophagus and along the inner aspect of the upper pole. The isthmus is palpated against the trachea (a parathyroid has been reported as having been found on the posterior aspect of the isthmus). If a pyramidal lobe is present it is exposed and palpated throughout its extent.

If the evidence of the existence of hyperthyroidism be certain by clinical and laboratory evidence, and still no parathyroid tumor has been found, and if digital palpation of the superior mediastinum demonstrates no palpable parathyroid tumor, the manubrium of the sternum may be removed to facilitate a visual search for a mediastinal parathyroid

adenoma since we have and Churchill likewise has demonstrated and removed a parathyroid adenoma from the superior mediastinum.

Should exposure of all these regions fail to demonstrate an adenoma of a parathyroid, it then becomes justifiable to remove and submit a normal appearing parathyroid to the pathologist for decision as to the possible pressure of hyperplasia of the parathyroids.

A brief abstract of the cases of hyperparathyroidism is submitted below together with X rays of the bones, illustrations of the location of the parathyroids drawn by the artist at the time of removal, the actual size of the adenoma of the parathyroid, a microscopic section of the tumor and follow up notes as to their postoperative course and changes in blood chemistry.

CASE REPORTS

CASE 1. Mrs. Rebecca B. aged 62 years, housewife, April 17, 1933. Patient came to the Clinic because of a progressive increasing deformity of the upper spine, a round back, and a loss of stature of some 5 years duration. The degree of this deformity is well illustrated in Figures 3, 4, and 5. There were likewise multiple diffuse generalized aches and pains.

Fig. 26. Case 4. Is this illustration made at the time of operation, a tracing of the outline of the removed parathyroid adenoma is shown demonstrating thus the actual size of the tumor.

Note the location of this tumor just below the horn of the thyroid cartilage suggesting that this adenoma probably arose in the superior parathyroid where it so commonly rests against the thyroid cartilage.

This tumor was entirely covered by thyroid tissue but could be moved upward and downward within the gland. Its relation to the recurrent laryngeal nerve which enters the larynx indicated by *x* at the level of the horn of the thyroid cartilage is to directly overlie it.

X-ray examination revealed the classical picture of a relatively advanced hyperparathyroidism. Figures 6, 7, and 8 are films of skull and spine showing the typical changes as described.

The initial blood calcium was 17.2 milligrams, the blood phosphorus 2.5 milligrams, and the phosphatase activity 64.4. Pre-operative estimation of these values showed an average calcium of 13.3 milligrams, and a phosphorus varying at times from 2.5 to 1.7 milligrams. The blood non-protein nitrogen averaged 30 to 35 milligrams. The phenolsulphophthalein test showed a kidney function of 25 to 35 per cent. There was a very slight trace to a slight trace of albumin in the urine, with some slight fixation of the specific gravity by 1 hour examination. It was evident that there was some renal damage. The basal metabolism was plus 20. On a fixed amount of calcium intake the patient was shown to be in negative calcium balance.

Operation was done on May 15, 1933. A parathyroid adenoma was excised (P.H.L.). Beneath the lower left pole of the thyroid there was a definite tumor mass which descended into the chest. This mass was 1.5 inches long and about three-quarters of an inch in diameter (Figs 9 and 10). It was distinctly separate from the thyroid gland, except for some connecting alveolar tissue and blood vessels. An immediate frozen section revealed parathyroid tissue, and further histological study confirmed the diagnosis of an adenoma of the left lower parathyroid gland (Fig. 11).

Following operation, the patient developed definite tetany on the evening of the third postoperative day. Blood calcium at this time was 8.5 and the blood phosphorus 1.2. Intermittent signs of tetany severe at times, persisted until the thirtieth postoperative day. The tetany was controlled by administration of parathormone and large doses of calcium lactate by mouth. Viosterol capsules were also given. On discharge from the hospital she was instructed to take 5 grams of tribasic calcium phosphate daily and continue with the viosterol, drops 5, twice daily at this time. The blood calcium was then 7.8 milligrams and the phosphorus 2.4 milligrams.

November 17, 1933. Six months following operation blood calcium was 9.5 and the phosphorus 4.3 milligrams. The phosphatase activity was 7.5. The patient was entirely free of her aching discomfort in the back and extremities. She had taken calcium phosphate in small doses up until this time and showed no evidences of tetany.

December 3, 1934. Eighteen and one-half months following operation the blood serum calcium was 10 milligrams and phosphorus 4 milligrams. The phosphatase activity was 3.7 Bodansky units. The patient had not taken calcium for 1 year. She revealed no signs of tetany and was entirely free from any symptoms.

CASE 2. Mrs. Anita K., aged 53 years, housewife. This patient is of particular interest in that she is the only one of the group here reported, presenting definite evidence of hypertrophic arthritis associated with hyperparathyroidism.

May 2, 1933. She was admitted to the clinic because of painful knees and pain in the back of the neck region of 4 to 5 years duration, slowly but progressively becoming more pronounced. She had been treated elsewhere without relief by tonics, tomy medication, and various other forms of diet.

The significant clinical findings were as follows: A well developed, fairly well nourished, very tired and worn appearing Armenian woman of 53 years with moderate upper dorsal round back, crepitations in knee joints, plus some periarthritic thickening, and definite limitation of motion of the head due to pain. These symptoms were at first thought to be due simply to pronounced fatigue, associated with a moderately advanced hypertrophic arthritis. X-rays of the knees, showing the lower femora, however revealed a diffuse, although not pronounced osteoporosis (Fig. 12). Parathyroid disease was therefore suspected. X-rays of the cervical vertebrae (Fig. 13) were even more suggestive of the same condition, although they also revealed extensive hypertrophic changes. Plates of the skull were negative. No tumor could be felt in the neck. The patient was then advised to enter the hospital for investigation of possible hyperparathyroidism.

The blood calcium ranged from 12.5 to 14.0 milligrams, the phosphorus 3 milligrams to 2.3 milligrams. Careful metabolic studies revealed a definite negative calcium balance. The urine calcium excre-

Fig. 27 Case 4. Photograph of parathyroid adenoma

tion was 0.328 grams to 0.423 grams. The blood phosphatase activity however averaging 10.2 units was approximately normal, but in view of the relatively insignificant bone changes, this phosphatase finding was not felt to contra indicate definitely the diagnosis of hyperparathyroidism. This patient is classified in group 2 and in view of the hypercalcemia and X ray findings described exploration of the neck was advised.

June 7, 1933 operation was done (FHL). A definite mass about equal to a medium sized olive was felt beneath the right inferior thyroid artery. Following demonstration of the recurrent laryngeal nerve, the inferior thyroid artery was ligated and the tumor mass revealed. With very careful dissection, it was freed from the nerve, delivered, and removed (Fig. 14). An immediate frozen section diagnosis of parathyroid adenoma was made and later confirmed by further microscopic study (Fig. 15).

On June 24, 1933, 17 days following operation, the blood calcium had come down from an initial high reading of 14.9 to 9.7 milligrams, while the phosphorus had risen from an initial low reading of 2.2 milligrams to 3.8 milligrams. The urine calcium with an original high reading of 0.462 grams diminished to 0.109 grams.

At no time was there evidence of postoperative tetany. The patient's aches and pains, however persisted, especially in the neck and knee region until September 1, 1933, 3 months following operation, when symptoms were much less pronounced.

September 19, 1934, 15 months following operation blood serum calcium 10.7 milligrams phosphorus 3.5 milligrams. Patient reported that aching discomfort was still intermittently present in the neck region, but the severity of these pains was much less pronounced. The knee joint symptoms had disappeared. She felt greatly improved over preoperative condition.

CASE 3. Mrs. Ellouse S. aged 74 years housewife. The diagnosis of hyperparathyroidism in this patient rests upon the history, the X ray findings, and upon the operative and microscopic demonstration of an adenoma of the parathyroid gland. The blood chemistry was normal. Metabolic study showed a slight negative calcium balance but no more than

Fig. 28 Case 4. Photomicrograph of parathyroid adenoma $\times 500$

might be present in conditions other than hyperparathyroidism.

June 2, 1933 she was admitted to the clinic with a complaint of gitter nervousness, and severe leg pains. Patient gave a history indicative of three spontaneous fractures in the region of the right knee and the right ankle and left ankle during the past 6 years. All had healed, but considerable deformity resulted particularly in the region of the right knee.

Figures 16 and 17 are X ray films of the spine and show marked decalcification with pronounced compression of the eleventh dorsal and second and fourth lumbar vertebrae. Small cystic areas are seen in the pelvis. Plates of the femora (Fig. 18) show an old malunited fracture of the distal end of the right femur, as well as a more recent fracture of the medial condyle of this femur.

The highest blood serum calcium finding was 11.3 the average of 4 estimations was 10 milligrams per hundred cubic centimeters. The blood phosphorus varied from an initial reading of 1.0 to 3 milligrams. The blood phosphatase activity was 7.2.

June 8, 1933 operation was done (FHL). The left thyroid lobe was occupied by a discrete adenoma the size of a lime, and a small adenoma about the size of a cherry both of which were removed, and on examination presented the typical gross and microscopic appearance of multiple colloid adenomatous gitter. Very careful palpation of the atrophic right lobe of the thyroid revealed a small discrete tumor about a centimeter in diameter in the substance of the gland at its superior pole. The actual size of this adenoma of the parathyroid may be seen in Figure 19 made by the artist at the operating table. This mass was therefore removed and on immediate frozen section showed parathyroid tissue. Further microscopic study revealed an adenoma of the right upper parathyroid gland (Fig. 20).

The postoperative course was quite uneventful. There was at no time any suggestion of tetany.

Fig. 20. Case 3. Lateral X-ray roentgenogram of spine showing the generally diffuse even decalcification of the column. Crushing of the body of first lumbar vertebra suggestive of fracture but there was no history of trauma. Note absence of involvement of intervertebral discs.

August 11, 1933, patient reported for check up examination at which time the calcium was 10.2 and the phosphorus 3.3 milligrams. The aches and pains in the legs were considerably improved. She was still having symptoms referable to the mechanical defect resulting from the malunited fracture, for which the patient refused any further therapy. Further studies of the renal function at this time as well as investigations before operation did not reveal definite evidence of a renal insufficiency. The urine remained negative and the blood non-protein nitrogen was 30 milligrams.

January 24, 1934, 6 months postoperative, the patient reported that she was not bothered by the leg pains except those due to old fracture of the right knee region. December 7, 1934, 18 months following operation the blood serum calcium was 10.0 and the phosphorus 4.1 milligrams. The blood phosphatase was 3.3 Bodansky units. The original complaint of nervousness and leg pains no longer bothered patient.

CASE 4. Miss Rachel E. aged 44 years, clerk. This patient was originally admitted to the clinic in January 1930, for a multiple colloid adenomatous goiter, partly substernal, without evidence of toxicity. Excision of the goiter was advised and carried out in October 1930, and the patient made an uneventful recovery. At this time there was no evidence of an adenoma of the parathyroid gland, nor were there any clinical signs of hyperparathyroidism.

The patient next returned to the clinic in June, 1934, because of diffuse low back pain and pain in the knees and legs of 2 years duration. In this interval, particularly in the past 10 months, the patient described a progressive loss of stature with an increasing round back deformity. Figure 21 is a photograph of the patient at this time. There was no evidence of a tumor in the thyroid region.

Figures 22 and 23 are lateral and anteroposterior X-ray films of the spine which reveal practically complete destruction of the fifth thoracic vertebra from marked compression. The pronounced deformity of the thorax is evident. A lateral view of the skull (Fig. 24) shows typical gross decalcification with prominence of the trabeculae and the soft mottled appearance of hyperparathyroidism. Numerous multilocular cysts as found in advanced cases of classical form of the disease are illustrated in the X-rays of the pelvis (Fig. 25). X-rays of the genito-urinary tract revealed the kidneys to be of normal size and regular in outline. There was no evidence of stone.

Initial blood serum calcium values ranged from 14.4 to 15.1 while the serum phosphorus varied from 2.4 to 3.5 milligrams. The phosphatase activity was 35 Bodansky units. The remaining findings from the complete blood study were negative. The basal metabolism was +14.

Operation was done July 9, 1934 (F.H.L.). A tumor mass was found in the lower lateral side of the remnants of the right lobe of the thyroid gland. This tumor, about the size of a large walnut, lay partly beneath the inferior thyroid artery. In Figure 26 is shown an actual outline tracing around the parathyroid adenoma. Immediate frozen section diagnosis was adenoma of the parathyroid which conclusion was later confirmed by paraffin sections. Figure 27 is a part of the parathyroid adenoma removed and Figure 28 is a photomicrograph of the adenoma.

The postoperative course was uneventful. The blood calcium immediately came down to 0.2 and the phosphorus to 3.1 milligrams. Two weeks after operation, the serum calcium was 8.0 and the phosphorus 3.0 milligrams. The patient did not develop typical tetany. She spoke only of some slight numbness of the finger tips, which lasted 4 to 5 days following operation.

October 18, 1934, 3½ months following operation, the patient's general condition was excellent. She was free from the aches and pains of which she originally complained while the blood chemistry findings remained normal. The blood serum calcium was 9.0 and that of the phosphorus 3.6 milligrams. Patient was taking 1 heaping teaspoonful of calcium lactate by mouth three times a day. Otherwise, she occasionally experienced slight twitching sensations in her legs. The clinical signs of tetany were negative.

December 21, 1934, 5½ months following operation, the blood serum calcium was 9.6 milligrams and phosphorus 3.1 milligrams. The general condition was excellent. Patient felt very much better than she

Fig. 30. Case 5. This parathyroid adenoma of the right inferior parathyroid was found at a location typical for inferior parathyroids at the point where they are most commonly seen in the course of thyroid operations.

The trunk of the inferior thyroid artery is shown and the course of the recurrent laryngeal nerve before it passes over or under the branches of the inferior thyroid artery. We have now dissected and visualized the recurrent laryngeal nerve several hundred times and are impressed with the fact that its course and location is dependably constant. Note that these tumors are not infrequently covered by a little thyroid tissue.

had at any time during the past 2 years. Her only complaint was occasional backache in the region of the kyphosis of the spine. These symptoms, however, were much less pronounced than they were before operation. She was continuing her calcium phosphate and lactate by mouth. No clinical signs or symptoms of tetany.

CASE 5. Mrs. Maude F. aged 52 years, housewife. February 22, 1934, patient entered the clinic because of aching pains throughout the body and a severe pain localized in the mid low back and running around into the abdomen. X-rays of the spine revealed a generalized decalcification. There was definite compression of the body of the first lumbar vertebra (Fig. 30). It was thought that these findings would adequately explain the patient's pain but in view of the decalcification of the bones, X-rays were also taken of the bones of the extremity and of the skull. The former were negative. The latter revealed a few mottled areas of irregular density with some actual thickening of the cortices. X-rays of the kidneys were negative for calculi.

The blood serum calcium ranged from 14.1 to 13.8 while the phosphorus varied from 2.1 to 2.0 milligrams. Phosphatase activity was 44.8 Bodansky units. The urine sediment revealed many white blood cells. The renal function test was normal.

Study of the X-rays of the spine first suggested that the compressed first lumbar vertebra might be the result of an old fracture, as there was definite increased density in the body of this bone. Paget's disease was considered. To rule out the possibility of any intraspinal pressure two lumbar punctures

Fig. 31. Case 5. Photomicrograph of parathyroid adenoma removed from this patient. $\times 500$.

were performed with normal dynamics and with clear spinal fluid. The total spinal fluid protein was 50 milligrams. There was a cell count of 1 and a colloidal gold of 1:121,100,000. The calcium estimation in the spinal fluid was 6.0 milligrams.

In view of the laboratory findings, the fact that the patient was in negative calcium balance, the demonstration of a multiple colloid adenomatous goiter and the probability of a tumor of the parathyroid—it was decided to explore the thyroid gland, remove the adenomatous goiter and search for a parathyroid adenoma. It was concluded that the patient presented strongly suggestive evidence of hyperparathyroidism and that she also probably had a mild form of Paget's disease.

March 10, 1934, operation was done (FHL). An exposure of the thyroid region revealed a marble sized adenoma of thyroid tissue in the left lower lobe. At the right inferior pole, the typical position of a parathyroid body, a discrete tumor the size of a large lima bean was found in immediate relationship to the inferior thyroid artery and the recurrent nerve. The parathyroid adenoma shown in the artist's drawing (Fig. 30) made at the operating table is about half the actual size. This mass was excised and on frozen section a diagnosis of parathyroid adenoma was made. This was later confirmed by complete histologic studies (Fig. 31).

Following operation the blood serum calcium was reduced to an average between 7.8 and 8.2 milligrams, while the phosphorus varied between 2.4 and 3.7 milligrams. Three days following operation the patient had a transitory attack of tetany with a positive Chvostek sign and numbness of the extremities. All symptoms of tetany were relieved by parathormone and by calcium lactate, grams 32 daily. She was discharged from the hospital 21 days after operation, entirely free from tetany. She was advised to continue 1 heaping teaspoonful of calcium lactate twice daily, 2 viosterol capsules, daily.

Fig. 32 a and b. An X-ray picture of the case of hyperparathyroidism seen in consultation with Dr. R. C. Cochrane. The two normal parathyroids had already been removed without relief of the hyperparathyroidism. At the suggestion of one of us (F.H.L.) an intrathyroid parathyroid adenoma was found and removed at a third operation. It is shown to demonstrate the advanced state of decalcification in Figure 32a and the very slight reaction in the cortex in Figure 32b, the point of a spontaneous fracture.

Following operative convalescence progressive hyperextension of the spine was instituted to prevent further compression of the first lumbar vertebra. This treatment had to be discontinued because the patient would not co-operate. We were successful in securing the patient's agreement to wear a high supporting corset.

May 15, 1934, 2 months following operation the blood serum calcium was 10.1 milligrams and the phosphorus 4.9 milligrams, while the phosphatase activity was 35.0 Bodansky units. It was necessary to administer parathormone subcutaneously and calcium lactate by mouth to prevent constant tingling sensations and numbness in the extremities.

July 13, 1934, 4 months postoperative this patient had gained 12 pounds in weight. Her chief complaint still was "kinking" in the low back. Blood serum calcium 11.2 milligrams, phosphorus 5.1 milligrams, and phosphatase 25.0 Bodansky units.

December 15, 1934, 8 months after operation, her general condition was still further improved. She had gained 10 pounds in weight. There were no clinical signs of tetany but she required calcium lactate (grains 45) daily by mouth, to feel good. The back pain referred to the lumbodorsal region was intermittently severe.

X-rays of the spine showed apparent normal calcification. The first lumbar body was compressed more than when first seen and was very dense. There was some early hypertrophic lipping of this vertebral

body and of the bodies of the adjacent twelfth dorsal and second lumbar vertebrae.

Blood serum calcium was 9.8 milligrams phosphorus, 3.5 milligrams and phosphatase, 5.8 Bodansky units.

The back pain is now due entirely to the mechanical derangement of the lumbodorsal spine as a result of the compression of the body of the first lumbar vertebra. Early hypertrophic changes have also appeared. To date patient refuses treatment for this condition (Fig. 32).

The hyperparathyroidism is relieved.

SUMMARY

Five new proved cases of hyperparathyroidism due to parathyroid adenomata are recorded together with the findings which lead to their diagnosis.

The clinical aspects, the blood chemistry and the bone changes are discussed.

The appearance of normal and abnormal parathyroids is discussed. The normal and abnormal location of parathyroids is presented in graphic form.

The five proved cases of hyperparathyroidism together with X-rays of the bones in these cases. Illustrations made at the operating table of the demonstration of the parathyroid tumors in such cases and microscopic slides of the tumor are submitted.

We must all particularly the orthopedist and the urologist be on the lookout for hyperparathyroidism in patients complaining of pain in the back or extremities, in patients with diffuse neuritis or arthritic pains made worse on motion in patients with progressive loss in stature and in patients with kidney stones. Many patients with hyperparathyroidism who could be relieved of their condition by surgical removal of a parathyroid adenoma have in the past and are doubtless still passing through our hands with their condition unrecognized.

MECHANISM, SYMPTOMS, AND TREATMENT OF HERNIA INTO THE DESCENDING MESOCOLON (LEFT DUODENAL HERNIA)

A PLEA FOR A CHANGE IN NOMENCLATURE¹

C LATIMER CALLANDER, M.D. F.A.C.S. GLANVILLE RUSK, M.D. AND
ALMA NEMIR, M.D. SAN FRANCISCO, CALIFORNIA

IT is our purpose in this paper to elaborate upon several phases of the so called left duodenal variety of intraperitoneal (internal) hernia. First we shall report a case of a complete rupture of this type an attempt will be made to explain the hernia on an embryologic basis reasons will be adduced to justify a change in the nomenclature of this lesion. The symptoms and signs consequent upon strangulation of the hernial contents and the methods of treatment of this variety of hernia will be mentioned.

REPORT OF CASE

A male E.S. 40 years of age, was admitted to the Mount Zion hospital because of rheumatic heart disease. His death in the hospital was the result of chronic mitral valvulitis, obliterative pericarditis, and lobar pneumonia. In the course of his hospitalization he gave no history and presented neither signs nor symptoms of the unusual intraperitoneal hernia which he presented at autopsy examination.

Our interest in the postmortem examination centered about an enormous hernial sac (Fig. 1) within which practically all of the jejunum-ileum was incarcerated. When the abdominal cavity was opened, the stomach, duodenum, liver and spleen were in their proper positions and had maintained their normal relationships. The cecum and the ascending, transverse, and descending divisions of the colon were in the normal inverted U position. The ascending and descending mesocolon and the segments of large bowel attached to the mesocolon were applied and normally adherent to the posterior parietal

Fig. Appearance of hernial mass of jejunum-ileum. The topography of the colon is normal. All but about 5 centimeters of the jejunum-ileum is incarcerated in the sac derived from descending mesocolon. In this drawing the neck of the sac is shown as open, blunt and sharp dissection was required to demonstrate the opening. The ascending branch of the inferior mesenteric artery and the inferior mesenteric vein are in the anterior wall of the neck of sac.

Fig. An incision was made in the peritoneal layer, in an avascular area, in the anterior wall of the hernial sac. The jejunum-ileum is seen through the rent in the sac.

Fig. 3 Dissection in recorded case of region about the transverse division of the duodenum and the initial jejunum. This drawing was made to show that the duodenum lay behind the superior mesenteric vessels. The colic angles are depressed to allow illustration of the distribution of the superior mesenteric vessels to the ascending and transverse colons.

peritoneum. The sigmoid colon was omega in shape and was suspended by a mobile mesentery.

Only the terminal 5 centimeters of the small bowel could be seen; the remainder of the jejuno-ileum lay within a hernial sac produced at the expense of the descending mesocolon and formed a large left-sided abdominal tumor. The forward wall of the hernial sac was the descending mesocolon, the serosal duplication of which contained the ascending branch of the inferior mesenteric artery and the inferior mesenteric vein, both of which stood out prominently. The location of the neck of the sac at first was not apparent for the reason that the margins of the orifice were united by peritoneal agglutination. However, blunt dissection about the duodenojejunal angle disclosed the neck of the sac which was a palm's breadth in length and demonstrated its several margins. There was no evidence of periduodenal folds or fossae. In the forward margin of the sac ran the ascending branch of the inferior mesenteric artery and the main trunk of the inferior mesenteric vein. In the inferior limit of the neck of the sac was the concavity of the upwardly arching course of the ascending branch of the inferior mesenteric artery. The superior boundary of the neck of the sac was the inferior mesenteric vein which ran in

a medial direction to contribute to the formation of the portal vein. The posterior boundary of the neck of the sac was the primitive midline attachment of the descending mesocolon.

An incision was made through the peritoneal layers which form the anterior wall of the sac, i.e. through an avascular area of the descending mesocolon and the jejuno-ileal contents of the sac were exposed (Fig. 2). Had strangulation taken place within the sac, an incision so placed as to avoid injury to the blood supply of the descending colon would have been used to determine the cause of obstruction and to restore alimentary continuity. Figure 4 shows all of the small bowel exteriorized through a large opening in the anterior wall of the sac. There were no adhesions between the contents of the sac and the sac wall.

The contents of the sac were then replaced and the intestinal coils were drawn to the right through the neck of the sac into the general abdominal cavity as is illustrated in Figure 5. It is evident that the root of the mesentery of the small bowel is much shorter than that found in the normal abdominal cavity. The drawing indicates the degree to which the inferior or distal coils of small bowel are bunched or clumped. The anatomical explanation for the

Fig. 4. All of the jejunum-ileum has been withdrawn through the rent in the anterior wall of the hernial sac. There are no adhesions between the hernial contents save at the neck of the sac.

Fig. 5. Mass of jejunum-ileum withdrawn through neck of sac into general abdominal cavity. The rent in the anterior wall of the sac noted in the foregoing drawings is retracted with hooks. The dissected area shows the upward course of the ascending branch of the inferior mesenteric artery and the inferior mesenteric vein. Both vascular trunks run in the anterior wall of the neck of the sac and constrict the sac orifice.

clumping of the distal loops of small bowel lies in the overlapping of the small bowel mesentery in its terminal portion. The mesentery at and near its root is compressed and partly turned upon itself to such a degree that two-thirds of the small bowel seem attached to that part of the mesentery which apparently has no more than 5 centimeters of posterior attachment.

Attempts made to separate the layers of peritoneum which form the walls of the sac were unsuccessful in demonstrating how many primitive layers were present before embryologic coalescence of opposed serous surfaces took place. A determination of the number of primitive peritoneal layers involved also was attempted by sectioning tissue blocks of the sac walls. The formation of coalescent fusion fascias rendered layer differentiation impossible.

GASTRO-INTESTINAL EMBRYOLOGIC BACKGROUND FOR INTERPRETATION OF THIS HERNIA

Before attempting to explain the variety of mechanisms by which this intraperitoneal hernia occurs it is necessary to review the essential stages in the development of the gastro-intestinal tract and its associated peritoneum.

The early alimentary canal traverses the future abdominal cavity of the embryo as a straight tube suspended from the dorsal wall by a common dorsal mesentery (Fig. 6). The tube is suspended anteriorly over the superior portion of its extent by the ventral common mesentery. As compared with the gradual growth of the embryo in length, disproportionately large growth occurs in the primitive digestive tube—one which results in the segmentation of the tube into its ultimate constituents, the stomach and the small and large bowel.

Differentiation of the tube results in a differentiation within its carrying mechanism, the dorsal and ventral mesenteries. These are subdivided into the dorsal and ventral mesogastric, the mesoduodenum and the mesenterics of the small and large bowel. The distribution of the branches of the aorta to each segment of the alimentary tube takes place

Fig. 6 Development of the gastro-intestinal tract from the primitive sagittal allmentary tube to the umbilical loop stage. A The primitive stomach is shown as a fusiform swelling with its greater curvature directed dorsally. The ventral mesentery extends a little beyond the stomach. B The gastric curvatures are more differentiated. The umbilical loop is suggested. The mesentery of the loop hypertrophies to accommodate the increase in length of the intestinal tube which forms the loop. C, The ascending limb of the loop at the point which marks the ileocecal junction, enlarges and forms the cecum, or beginning of the initial segment of the colon. D The small intestine segment of the loop (jejunum-ileum) increases in length, as shown by the fluting. The differentiation of the dorsal common mesentery into segments is indicated.

while the tube and mesenteries are in the primitive sagittal position.

The structural changes in the tube are not all those of simple elongation for there are changes in form and capacity as well. The cephalic portion of the canal bulges into a fusiform swelling the stomach. The middle portion lengthens into the redundant umbilical loop of which the descending limb and part of the ascending limb constitute small intestine and the remainder of the ascending limb becomes the initial part of the large bowel. The terminal part of the alimentary tube is transformed into a long uniformly large segment the remainder of the large bowel.

While these changes occur the glands annexed to the digestive tract develop between the peritoneal duplications which make up the dorsal and ventral mesenteries, these are the liver spleen and pancreas. The spleen develops independently of the gastro-intestinal tube but the liver and pancreas arise as outgrowths from it (Fig 7).

The rotation and posterior fixation of the gastroduodenal segment of the alimentary tract will not be discussed at length because the changes which take place in this segment have no bearing upon the mechanism of left duodenal hernia. The stomach in this rotation is the central and pivotal viscus. The first rotation of the stomach is about its long

Fig. 7 Diagrammatic sagittal section of an embryo at the completion of the umbilical loop stage of development. The celiac artery supplies the gastroduodenal segment, the superior mesenteric artery the umbilical loop, and the inferior mesenteric artery supplies the terminal intestine. (Callander's *Surgical Anatomy* Courtesy W. B. Saunders Co.)

Fig. 8 Sagittal diagram of the umbilical loop and terminal intestine segments prior to rotation. In A, the umbilical loop is attached, and in B it is removed to show the distribution of the superior mesenteric artery. The superior mesenteric artery is the axis of the loop about which rotation occurs. The inferior mesenteric artery is the vascular supply of the terminal intestine. (Callander's *Surgical Anatomy* Courtesy W. B. Saunders Co.)

Fig. 9. Umbilical loop segment after a counter clockwise rotation of 90 degrees. In A, the loop maintains its duodenal and terminal colon connections. In B the ascending and descending limbs of the loop are removed to show the disposition of the mesentery and the enclosed arterial supply. The arrow indicates the direction of the succeeding stage of rotation (Callander's *Surgical Anatomy* Courtesy W B Saunders Co)

Fig. 10. Disposition of the structures formed from the umbilical loop after its rotation to the oblique colon stage. In A, the elements of both limbs of the loop maintain their duodenal and terminal colon connections. In B the elements of both limbs of the loop are removed (Callander's *Surgical Anatomy* Courtesy W B Saunders Co)

axis and the second rotation about its antero-posterior axis. The rotation of the stomach upon its anteroposterior axis folds the initial part of the primitively sagittal duodenum and its mesentery and contents against the right primitive parietal peritoneum, to which they become fused by the process of fetal peritoneal 'agglutination'

An understanding of the rotation and posterior fixation of the umbilical loop segment of the gastro-intestinal tract is essential to the comprehension of the mechanism of left duodenal hernia. We have referred to the initial part of the duodenum as having been brought to the right across the median line by the rotation of the stomach about its antero-

Fig. 1. Final stage of umbilical loop rotation. In A, the intestinal structures are in place after the completion of rotation and the formation of the ascending and transverse colon segments from the oblique colon. In B most of the ascending colon and mesocolon and the jejunum-ileum and its mesentery are removed. The superior mesenteric artery is the boundary between the mesentery of the ascending colon and the mesentery of the jejunum-ileum (Callander's *Surgical Anatomy* Courtesy W. B. Saunders Co.)

Fig. 2. Diagram to show the mesenteries of the ascending, transverse, and descending portions of the colon in their ultimate positions prior to posterior peritoneal fixation. The jejunum-ileum is cut away to show its mesentery which remains mobile. The root of the mesentery is along the line of the superior mesenteric artery (Callander's *Surgical Anatomy* Courtesy W. B. Saunders Co.)

posterior axis. The distal part of the duodenum is the connection between the gastroduodenal segment and the umbilical loop. The colic angle or the inferior connection of the loop is the junction between the distal end of the umbilical loop and the terminal intestine. The ultimate position of the terminal part of the duodenum is dependent upon the rotational changes of the umbilical loop since these changes affect the position of the superior and inferior connections or points of suspension of the loop the former of which includes the terminal duodenum.

In order to make clear the various changes in position undergone by the umbilical loop it will be helpful to follow these changes in position as illustrated in Figures 8 to 11 inclusive as though one were producing them manually.

Fig. 13 Diagram of the duodenum and mesoduodenum after rotation of the gastrointestinal tube. The diagram shows how these structures are applied and fixed to the underlying peritoneum: the descending duodenum and part of the transverse duodenum are applied to and fuse with the primitive right parietal peritoneum. The remainder of the transverse duodenum and the ascending duodenum are applied to and fuse with the descending mesocolon. The duodenojejunal angle fuses partly with the inferior part of the transverse mesocolon (Callander's *Surgical Anatomy* Courtesy W B Saunders Co)

After rotation is complete the ascending, transverse, and descending portions of the colon are illustrated as having been carried to their ultimate position of an inverted U with the loops of the jejunum and ileum surrounded by the large bowel as by a frame. The key to the permanent and fixed arrangement of the segments of the gastro-intestinal tract lies in the manner of their posterior peritoneal fixation. The cecum, ascending colon, and the ascending mesocolon fuse with the right primitive parietal peritoneum over that area included between the trunk of the superior mesenteric artery and the lateral margins of the ascending colon. The transverse colon and mesocolon do not fuse with the primitive and mesocolon do not fuse with the primitive posterior parietal peritoneum but make up a more or less mobile unit. Posterior peritoneal agglutination binds the descending colon and mesocolon to the left primitive parietal peritoneum.

Our interest in recording the steps in gastrointestinal fixation centers about the terminal duodenum. It will be noted by referring to Figure 13 that the terminal duodenum and its mesentery and the continuous mesentery of the transverse and descending colon are superimposed structures before peritoneal agglutination takes place. The descending

mesocolon fuses with the left parietal peritoneum, and the ascending duodenum and its mesentery and the duodenojejunal angle fuse to the underlying mesocolon. The degree of fixation of the terminal duodenum to the mesocolon determines the strength of adhesions which bind down this segment of bowel to the mesocolon. If the adhesion of the duodenum to the mesocolon is strong the superior and inferior duodenal (duodenojejunal) folds are shortened and the recesses they roof (superior and inferior duodenal fossae) are shallow and small. If, on the other hand, the adhesion of the duodenum and its mesentery to its mesocolon is loose then these folds are large and the fossae which they roof are broad and deep.

THE FOSSAE ABOUT THE TERMINAL DUODENUM

In an analysis of the mechanism of hernia into the descending mesocolon a detailed description of the recesses about the terminal duodenum must be given because one or several of these fossae undoubtedly may be the point of entrance of small bowel in the development of this type of rupture. The most important of these recesses are the superior

Fig. 14. A, Topography of the duodenojejunal junction and periduodenal folds and fossae. The arrangement of the vessels in the descending mesocolon as indicated. B, The most important periduodenal folds and fossae. Attention is directed to the course of the vascular trunks noted in A. They run in the fold overhanging the periduodenal fossa (of Landzert). (Modified from Callender's *Surgical Anatomy* Courtesy W. B. Saunders & Co.)

duodenal inferior duodenal, and the para duodenal fossae.

The superior duodenal fossa is the most constant of the peritoneal depressions situated about the ascending portion of the duodenum and to the left of the termination of this segment of the small bowel. The fossa lies at the level of the second lumbar vertebra and is bounded anteriorly by the superior duodenal

fold, a duplication of peritoneum which is essentially an embryological adhesion between the termination of the duodenum and the inferior surface of the transverse mesocolon near its union to the descending mesocolon. The inferior or free margin of the fold is concave, its mesal extremity blending with the peritoneum over the anterior surface of the terminal duodenum and its lateral extremity

Fig. 15 Invagination of periduodenal fossa and later of descending mesocolon by initial knuckle of jejunum. The invagination is mainly into the paraduodenal fossa (of Landzert)

fusing with the ultimate parietal peritoneum at the junction of the transverse and descending mesocolon 1 c, anterior to the left kidney. The lateral attachment of the superior duodenal fold may be mesal or just lateral to the course of the inferior mesenteric vein, hence the designation of this fold as a 'vascular plica'. The orifice of the superior duodenal fossa looks inferiorly and its apex extends superiorly sometimes as far as the body of the pancreas.

The inferior duodenal fossa (of Treitz) lies to the left of the ascending portion of the duodenum on a level with the third lumbar vertebra. Its orifice looks superiorly directly into the orifice of the superior duodenal fossa. The closed end of the fossa points inferiorly and to the right toward the mesentery of the proximal jejunum. The cavity is bounded anteriorly by the inferior duodenal fold the free margin of which is thin and sharply demarcated. Its medial extremity blends with the peritoneum over the anterior surface of the ascending duodenum and its lateral

Fig. 16 Position of the small and large bowel at end of first stage of rotation. The arrow indicates the direction taken by the jejunum-ileum in invaginating the postarterial mesentery (ultimate ascending and transverse mesocolon). This drawing is explanatory of Haymond and Dragstedt's case of anomalous rotations. This and the following drawings were made as modifications of their drawings in an attempt to illustrate in 3 dimensions the anomaly they report.

Fig. 17. Invagination of the postarterial mesentery by the small bowel. The duodenum, instead of rotating counter-clockwise behind the superior mesenteric artery crosses anterior to the artery and is beginning to invaginate the postarterial mesentery (ultimate ascending and transverse mesocolon). The initial colic segment ultimately will become the ascending and transverse divisions of the colon.

extremity fuses with the peritoneum of the descending mesocolon (ultimate posterior parietal peritoneum). The inferior mesenteric vein and left colic artery usually lie well to the left of the lateral attachment of the inferior duodenal fold although occasionally this

Fig. 19. Invagination of the postarterial mesentery by the small bowel. The mass of small bowel continues to invaginate the postarterial mesentery. The initial colic segment now rotates and elongates until the ascending and descending divisions of the colon are visualized.

Fig. 18. Invagination of the postarterial mesentery by the small bowel. Much of the duodenum and jejunum now has pocketed itself into the postarterial mesentery. The oblique colon as yet has not become differentiated into the ascending and transverse colon.

vein has been found in the posterior wall of the fossa under discussion. The inferior duodenal fossa usually can accommodate the first phalanx

Fig. 20. Invagination of the postarterial mesentery by the small bowel. The divisions of the colon now are in their normal positions. The mass of jejunum-ileum is contained in a sac derived from postarterial mesentery. Most of the sac and contents lie to the left of the midline. Both the duodenum and terminal ileum cross anterior to the superior mesenteric artery. This schema represents the final stage in the production of the anomaly observed by Haymond and Dragstedt.

Fig. 21. Invagination of the postarterial mesentery by the small bowel. This drawing is a photograph of Haymond and Dragstedt's anomaly. Incision of the postarterial mesentery (ascending and transverse mesocolon) shows the contents of the sac at autopsy. It is obvious that the duodenum and the terminal ileum run anterior to the superior mesenteric artery. (From Haymond and Dragstedt, *Surg Gynec. & Obst.* 1931 53:323)

of the middle finger. Occasionally the fossa extends into the region posterior to the ascending portion of the duodenum a result of inadequate peritoneal fixation of this portion of the bowel.

The *paraduodenal fossa* (of Landzert) frequently exists in conjunction with the fossa just described. It is located at the left and quite a distance from the ascending portion of the duodenum and is a cavity produced by the elevation of a fold of peritoneum by the inferior mesenteric vein. This fold has been aptly termed the fold of the inferior mesenteric vein in its course within the descending mesocolon; hence, the varying distance from the terminal duodenum of the peritoneal fold which contains this vessel. The floor of the paraduodenal fossa is the peritoneum of the descending mesocolon

(ultimate posterior parietal peritoneum). The mouth or neck of the fossa is wide and opens inferiorly and to the right, and its closed extremity is directed superiorly and to the left. When the paraduodenal fossa occurs in conjunction with the superior or the inferior duodenal fossa or with both there usually is an amalgamation of the folds roofing the orifices of the fossae.

The *posterior or retroduodenal fossa* occurs occasionally especially in conjunction with a large paraduodenal fossa. The posterior duodenal fossa lies immediately behind the superior part of the ascending division of the duodenum, and is the result of a lack of fusion between the terminal part of the duodenum and the underlying ultimate posterior parietal peritoneum (primitive descending mesocolon).

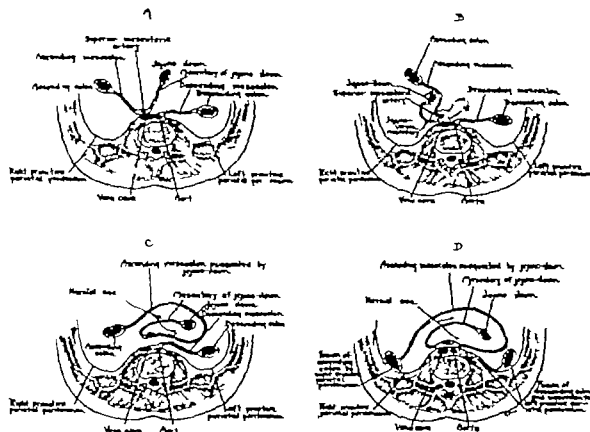

Fig. 23 Series of cross sections showing invagination of the postarterial mesentery by the small bowel. A, indicates the level at which invagination occurs. The jejunum-ileum and ascending colon are on a continuous mesentery. The ascending and descending mesocolons as yet are not fused to the posterior parietal peritoneum. The jejunum-ileum occupies its normal position after proper rotation has taken place. In B, the small bowel is illustrated as not having gained its normal position, as in A, by rotating behind the superior mesenteric artery but by rotating clockwise and

invaginating the ascending mesocolon. In C, the small bowel continues to invaginate and makes a hernial sac of the ascending mesocolon. The ascending colon is dropping down, preparatory to fusing with the right primitive parietal peritoneum. In D, the ascending colon has fused with the right primitive parietal peritoneum. The descending colon and the mesocolon have fused with the left primitive parietal peritoneum. The small bowel is enclosed in a hernial sac which is comprised of the ascending mesocolon.

There can be little doubt that the peritoneal duplications which delimit the periduodenal fossae are fusion or adhesion folds which are the result of fetal agglutination or fixation. We have noted in the section devoted to the development of the gastro-intestinal tract how the terminal duodenum is rotated against, and becomes adherent to the free peritoneal surface of the transverse and descending mesocolon. Hyperfixation which results in strong agglutination of the opposed surfaces, makes for short folds and shallow fossae. Hypofixation results in longer folds and deeper fossae. Adhesions have been noted in the embryo in this region at the middle of the fourth fetal

month. At this early stage these adhesions are delicate and non resistant. In embryos of greater age the adhesions are denser and are capable of withstanding considerable tension.

THEORIES OF HERNIA DEVELOPMENT

Accredited mechanism of hernia development. As a result of the fundamental work by Treitz, Moynihan, Landzert Broesike, and others, the genesis of the so called left duodenal type of hernia has been associated with the periduodenal fossae. Almost all investigators of the lesion agree that it usually begins in early fetal life. The initial portion of the jejunum is assumed to be invaginated into

Fig. 23. Drawing indicating successive positions of large bowel and the mesocolon. The numbers indicate the stages in the progressive increase in size and in the placement of the large bowel and mesocolon.

the paraduodenal fossa (of Landzert) or into the inferior duodenal fossa (of Treitz) or into a combined fossa (of Treitz and Landzert). By a mechanism altogether obscure the bowel gradually enlarges the fossal sac until a smaller or greater part of the jejuno-ileum is invaginated and lost to view.

That the periduodenal fossae with their overhanging folds do offer areas of easy engagement for the small bowel is incontrovertible, it seems certain that many small ruptures of the type of hernia under discussion occur in which the periduodenal folds and fossae are clearly delimited and the fossae are occupied by one or more knuckles of small bowel. It is to be expected that the anterior part of the neck of the sac contain one or more of the constricting trunks of the inferior mesenteric vein and the ascending branch of the left colic artery.

It is still a matter of conjecture whether the hernia develops altogether *in utero* or whether the enlargement of the sac continues after birth. It seems reasonable to assume that the

sac reaches its maximum size in fetal life since during part of that period the descending colon is attached to a mesocolon sufficiently mobile to be invaginated easily and to contribute to the formation of a sac. There are those however who insist that the enormous sac required to house virtually all the jejuno-ileum may be formed after the primitive mobile descending mesocolon has been fixed to the primitive left parietal peritoneum.

In assuming that one of the periduodenal fossae particularly the paraduodenal fossa is the point of origin of this rupture and that these fossae are depressions in the descending mesocolon it is necessary also to assume that this increase in the size of the sac must be at the expense of the descending mesocolon. This must be by the progressive process of invagination irrespective of the size which the hernia attains.

Invagination of the combined ascending and transverse mesocolon (post-arterial mesentery) by the small bowel. Haymond and Dragstedt have described a most unusual type of intra

Fig. 24. Diagram of small and large bowel and their attached mesenteries in a stage of almost complete rotation. Posterior peritoneal fixation has not occurred as yet. The stippled area in the continuous transverse and descending mesocolons indicates the vascular area invaginated, according to our hypothesis, by the coils of jejunum-ileum before posterior peritoneal fixation has taken place.

peritoneal hernia. Their hernia is the result of an anomaly in the second stage of gastro-intestinal rotation in which the jejunum-ileum comes to occupy an abnormal position by invaginating the mesentery of the primitive ascending and transverse colon. We have modified certain drawings of these authors and have regrouped them in an attempt to make more clear the mechanism of the hernia they describe.

Figure 16 illustrates the midgut at the end of the first stage of rotation when the mass of jejunum-ileum is in the right side of the abdomen and the segments of large bowel are in the left. Figure 17 indicates that the jejunum-ileum instead of rotating counter-clockwise about the superior mesenteric artery as an axis, rotates clockwise and invaginates the primitive mesentery of the ascending and transverse colon (post arterial mesentery). When all the small bowel has invaginated this mesentery (Figs. 20 and 21) the duodenum of necessity crosses anterior to the trunk of the

superior mesenteric artery and not posterior to it, as would be the case were small bowel rotation normal and therefore counter-clockwise (Fig. 10). The drawings (Figs. 16 to 23) indicate the manner in which the small bowel invaginates the post-arterial mesentery until all of the small bowel is in the mesentery as if in a sac.

No case of hernia into the descending mesocolon possibly can arise in this manner because the sac formed by the ascending mesocolon separates the hernial contents from any contact with the descending mesocolon (Figs. 17 to 21). The descending colon and descending mesocolon in the instance of malrotation under discussion are entirely normal in development, rotation and posterior fixation.

A series of cross sections through this anomaly (Fig. 22) indicates how much the condition differs from that of hernia into the descending mesocolon (Fig. 27).

Proposed mechanism of development of hernia into the descending mesocolon. In the

Fig. 25. Well advanced invagination of the as yet mobile descending mesocolon by coils of jejunum-ileum. It is evident that the sac is formed at the expense of the avascular area of descending mesocolon. Attention is drawn to the vascular trunks in the anterior wall of the neck of the sac.

development of a large hernia such as we are reporting we believe that a mechanism can be postulated which does not presuppose that the small bowel invaginate the periduodenal fossae, a fanciful theory in large ruptures. It seems logical that the loops of jejunum-ileum as they pass normally behind the superior mesenteric artery as in Figure 24 to Figure 26 invaginate the mobile descending mesocolon in its upper segment and within an area outlined by definite boundaries.

Before describing direct invagination of the descending mesocolon attention is called to Figure 23 which shows all the divisions of the large bowel and their continuous mesenteries lying unfixed. Their progressive changes of position to ultimate placement in the abdominal cavity is indicated numerically. Figure 14 indicates that the descending mesocolon has its root at the midline of the dorsal wall of the embryo. Between the leaves of the peritoneal duplication which forms the descending mesocolon the ascending branch of the left colic artery runs superiorly and somewhat laterally.

The inferior mesenteric vein also lies in the mesocolon and its main trunk is directed superiorly and mesially to combine with the superior mesenteric and splenic veins to form the portal vein. The artery and vein just mentioned usually run superiorly at some distance from the midline root of the mesocolon thereby leaving a very considerable avascular space between the ascending branch of the inferior mesenteric artery and the inferior mesenteric vein and the root of the descending mesocolon. This interval is indicated by an area of stippling. The closer to the descending colon these vessels lie the larger is the avascular interval of descending mesocolon.

It is our belief that in many cases of hernia into the descending mesocolon (so called left duodenal hernia) the upper jejunum and ileum in their migration to the left superior part of the abdominal cavity engage to a greater or lesser degree into the unsupported area of descending mesocolon just described. The mesocolon then falls to the left and fuses to the primitive posterior parietal peritoneum.

Fig. 26. Almost complete invagination of jejunum-ileum into descending mesocolon. This drawing represents the condition found in the case we are reporting. Compare it with Figure 1.

When the coils of small bowel invaginate the mesocolon the vascular trunks located in the left margin of the avascular area resist invagination. The result is that these trunks then lie in the forward wall of the neck of a sac all of which is derived from the avascular area of the descending mesocolon. Gradually all of the small bowel may enter the enlarging sac.

The series of changes resulting from the small bowel invagination of the descending mesocolon, while the mesocolon still is mobile, is illustrated in the series of cross sections in Figure 27. After all of the small bowel has entered the sac, the peritoneal surfaces outside the sac undergo fusion.

PLEA FOR A CHANGE IN NOMENCLATURE IN SO CALLED DUODENAL HERNIA

It must be evident that the duodenum with the occasional exception of its terminal portion is not an element in the hernial contents of the so called duodenal or paraduodenal hernia. Nor does the duodenum figure in any of the other varieties of so called duodenal hernia. It is the jejunum and ileum which are the contents of the sac. Inasmuch as part or

all of the small bowel invaginates the descending mesocolon in the type of hernia under discussion it is proposed that the so called left duodenal types of rupture be known rather as hernia into the descending mesocolon.

In a succeeding paper reasons will be adduced to justify a change in the name of that variety of intraperitoneal hernia known as "right duodenal hernia" to hernia behind the ascending mesocolon." The anomalous rotation of the jejunum-ileum reported by Haymond and Dragstedt should not be classed with either of these varieties of intraperitoneal hernia to that we wish to ascribe the name of hernia into the ascending mesocolon.

SYMPTOMS AND SIGNS OF HERNIA INTO THE DESCENDING MESOCOLON

The hernia we have described caused no symptoms and produced no physical signs. Many herniae with a similar lack of clinical manifestation have been found in a course of laparotomy for other conditions and during routine autopsy examination.

When however obstruction occurs in the bowel incarcerated within the hernial sac, an exact diagnosis of this type of internal hernia

Fig. 27 Series of cross sections through region of development of hernia into descending mesocolon. A, In this section the jejunum-ileum and ascending colon are attached to a common mesentery and are mobile. The descending colon and mesocolon are mobile. Attention is drawn to the position of the inferior mesenteric vein in the descending colon. B The jejunum-ileum has begun to invaginate the avascular area of the descending mesocolon between the

inferior mesenteric vein and the midline attachment of the mesocolon. and a sac is in the process of formation. C, The jejunum-ileum has invaginated the avascular area of the descending mesocolon deeply and a larger sac is being formed. For clarity only one loop of small bowel is shown in the sac. D The opposed serous surfaces now fuse by the process of fetal agglutination. The colon and mesocolon now are fixed to the posterior abdominal wall.

sometimes has been, and in the future more often will be made. Considerable diagnostic importance should be placed upon the history of chronic intestinal obstruction. One in duvidual found to have this type of hernia suffered 40 different attacks of intestinal obstruction prior to the one which precipitated operation. If the signs and symptoms are only those of acute intestinal obstruction an exact diagnosis is difficult to make.

Certain signs sometimes are present which are of great value. A soft tumor in the left side of the abdomen several times has been found in the reported cases of hernia into the descending mesocolon but the swelling usually has been misdiagnosed as an ovarian or a

pancreatic cyst. The occurrence of one or more attacks of intestinal obstruction in addition to the presence of tumor should lead one to a consideration of the possibility of an intra peritoneal hernia.

At times the location and physical findings of the tumor are distinctive. Palpation may reveal the swelling as occupying the superior part or all of the left side of the abdomen. Percussion over the tumor should yield a resonant note, and the auscultatory findings may be those of gurgling peristalsis. The size and tension of the tumor mass and the degree of peristalsis depend upon the amount of obstruction in the incarcerated contents of the sac.

TREATMENT

The treatment of hernia into the descending mesocolon may be simple or extremely difficult. The operative results in the last 10 years have been much more favorable than those in earlier years—the consequence doubtless of more timely recognition of obstruction within the sac and earlier surgical intervention.

In several patients with small herniae, the incarcerated bowel was drawn out without difficulty into the general abdominal cavity through the neck of the sac, which was closed by suture. In occasional instances the serious condition of the patient has precluded the closing of the neck of the sac after withdrawal of its contents. On at least one occasion in a person so treated adhesions developed spontaneously about the orifice of the sac, and the hernia did not recur. In some herniae even of small size, manual reduction could not be accomplished under these circumstances. It might have been possible to loosen the neck of the sac by making a small incision in a superior and medial direction so that the vascular trunks in the forward walls of the neck could be avoided. It must be borne in mind constantly that the inferior mesenteric vein lies not only in the lateral margin of the neck of the sac but often courses medially in its superior portions in such a way as to preclude any incision in the neck of the sac.

In a very large hernia in which nearly all the jejunum-ileum lies within the hernial sac, the sac orifice usually is so constricted that the contents of the sac cannot be brought into the general abdominal cavity even when no adhesions at the neck of the sac are present. In the case we are describing the neck of the sac was small and the adhesions about it were so adherent that painstaking blunt, and sharp dissection were required to locate it. Had intestinal obstruction within the sac occurred, it would not have been possible, because of these adhesions, to have delivered the hernial contents into the general abdominal cavity. The only possible recourse in the treatment of such a situation would have been incision of the anterior wall of the sac (descending mesocolon) in an avascular area and the emptying of the dilated bowel by temporary enterostomy. After ascertaining and relieving the cause of

the obstruction the rent in the anterior wall of the sac should be closed.

SUMMARY

1 An instance is reported of herniation of practically all of the jejunum-ileum into the descending mesocolon (so called "left duodenal hernia").

2 The embryologic background of intestinal rotation and posterior peritoneal fixation is portrayed in order that the varieties of mechanism of production of this type of hernia can be understood.

3 A detailed description of the folds and fossae about the terminal duodenum is given so that the rôle they play in the production of this hernia may be interpreted properly.

4 In this paper it is suggested that hernia into the descending mesocolon occurs as a result of invagination of an area of the descending mesocolon by the jejunum-ileum while the descending mesocolon is mobile. A location in the descending mesocolon for the reception of the invaginating jejunum-ileum is indicated.

5 A change in nomenclature for the so called "left duodenal" type of intraperitoneal hernia is advocated. From the embryologic and anatomic viewpoints, this hernia should be known as a hernia into the descending mesocolon.

6 The salient features in the recognition and treatment of hernia into the descending mesocolon are enumerated.

We are indebted to Dr. John B. de C. M. Saunders for his constructive criticism and suggestions in relation to the embryological discussion in this paper.

THE USE OF VITAL STAINING AND WET FILMS IN THE DIAGNOSIS OF LESIONS OF THE CERVIX

R. K. BOWES, F.R.C.S. (Em.), M.S. (LOND.) LONDON, ENGLAND
Chief Assistant to the Obstetrical Department of St. Thomas' Hospital

N. R. BARRETT F.R.C.S. (Em.), M.Chir. (CANTAB.), LONDON, ENGLAND
Chief Assistant to the Surgical Unit, St. Thomas' Hospital

THE introduction by Schiller of a new and simple test for establishing the diagnosis of carcinoma of the cervix was of such interest and importance that the method has been tried at St. Thomas's Hospital upon a representative series of cervical lesions.

In the original paper Schiller pointed out that cancer of the cervix starts in the squamous epithelium in the vicinity of the os and spreads laterally and superficially from this point. The earliest changes consist of a proliferation of the squamous cells and the surface remains intact for some time before ulceration occurs. To locate these early patches of new growth a method of vital staining which differentiates normal from malignant epithelial cells was devised and small portions of suspicious material were removed for microscopy. As regards this method of vital staining it was pointed out that the normal squamous cells of the cervix contain granules of glycogen and that these granules could be stained vitally with Lugol's iodine. Schiller also stated that in some pathological conditions, and notably in early cases of carcinoma when the surface had not ulcerated glycogen was absent from the squamous cells and vital staining did not occur. He claimed therefore, that by using Lugol's solution it is possible to make a diagnosis of carcinoma earlier than by the usual clinical means.

Since the publication of this work in SURGERY GYNECOLOGY AND OBSTETRICS, several other investigators, particularly Graves and Frank, have endorsed these views and have stated that they are very much impressed by the value and possibilities of the method. Our own opinions are not in entire agreement with those which have been recorded by others, and the object of this paper is to state the value of vital staining as applied to lesions of the cer-

vix in general the drawbacks and difficulties in cases of carcinoma and to advocate the use of 'wet films' for the immediate investigation of pieces of tissue removed for biopsy.

The cases we have examined have practically all attended the Out Patient Department, and include normal cervixes, erosions, ectropion of the canal, extrusion of the mucosa, polypi traumatic conditions, and carcinomata both of the cervical canal and vaginal cervix.

The technique we have adopted is as follows. A speculum is passed after bimanual examination has been done, and the cervix is examined macroscopically. Mucus or other secretion is carefully wiped away and the surface of the cervix and vaginal vault is painted with Lugol's solution. The excess of iodine is sponged away and the reaction of the parts noted. In every instance small pieces of tissue from suspicious areas are removed and from these wet films are made immediately. The preparation of these films will be discussed subsequently.

The material for biopsy was obtained by a special punch¹ which we recommend to any who may wish to secure such material easily without causing inconvenience to the patient. Small pieces can be removed from the cervix without pain, even in cases of cervicitis, and on only one occasion have we had any trouble from bleeding.

Clinically our cases fall into three main groups when judged by the reaction of the cells to the vital stain.

In the first group are those in which the cervix and vaginal vault stain diffusely evenly and deeply. The reaction occurs almost as soon as the solution has been applied. This is the reaction of the normal cervix and apart from certain qualifications is fairly constant.

Made by Messrs. Allen and Hanbury to our order.

The depth of the stain varies to some extent with the age of the patient, and in the light of the work of Cruickshank and Sharman this is not surprising, for they have demonstrated that the glycogen content of the epithelium steadily diminishes after the menopause until in extreme old age it is very difficult to find any glycogen in the cells at all. This fact must be important in interpreting results of vital staining in old people. Again there are many cervixes which show clinical evidence of tears and cervicitis which stain in the normal way and finally it must be remembered that since the columnar epithelium of the cervical canal does not contain glycogen there will be a ring of unstained tissue round the os in cases suffering from ectropion of the mucosa.

The second, and perhaps the most common group of cases is those in which the cervix presents a mottled appearance due to patches of light brown or lemon yellow color among the normal dark stain. A peculiar feature of these patches is that they do not correspond to clinical lesions which are apparent macroscopically, on several occasions we have noted these patches in what we had judged to be a normal cervix. One is therefore forced to the conclusion that other factors influence vital staining apart from pathological conditions. The mottled cervix is most often seen in cases of erosion polypoid conditions cervicitis and in carcinomata which have ulcerated. It has been pointed out by other observers that pus on the surface of a lesion stains brown or black with the iodine and it is important not to overlook cases of early malignant ulceration when obscured in this manner. In our series we have seen only one case of carcinoma in which the surface of the growth had not ulcerated and this was a patient who was pregnant and who was found to have an early polypoid growth involving the posterior lip of the cervix. Lugol's iodine gave a mottled appearance and we were in doubt as to the correct diagnosis until the wet film had been examined. Sections made from the tissue removed confirmed the diagnosis and the tumor proved to be a squamous cell carcinoma. This case supports the view which has been expressed by others that is that pregnancy may interfere with the test.

Fig. 1. Film showing plaque of normal cervical mucosa and acute polymorphonuclear inflammation. The regularity of the nuclei, the presence of cell membranes between the individual cells, and the even staining are the features which indicate the benign nature of this epithelium. $\times 330$.

The third clinical group is those in which there are absolutely white and unstained areas and we consider that the distinction between this complete absence of staining and the lightly stained areas in the mottled cervixes described has not been sufficiently emphasized. In these areas the cells are not even colored light brown by the iodine and they stand out in marked contrast to the dark brown of the vital stain. These areas according to Schiller indicate—

- 1 The presence of carcinomatous layers or incipient cancer
- 2 The presence of hyperkeratosis, a result of prolapse
- 3 The presence of hyperkeratosis of luetic origin
- 4 Desquamation of the superficial layers of the epithelium by trauma

In our series we have found that the lesions mentioned in this list are more frequently associated with a mottled or light staining and those in which we have found white patches have been fungating carcinomata areas of trauma which extended deeper than the epithelial layer, and occasionally in old scars and fibrous lesions.

Fig. 2. Normal squamous epithelium showing the gradual change from the basal layers to the superficial decussating cells on the surface. $\times 75$

Considering these results as a whole they show that the staining properties of Lugol's iodine are inconstant and difficult to interpret and are influenced by factors apart from pathological lesions. When it is remembered that cases of cancer of the cervix in the pre-ulcerative state are rare and that normal staining of the cervix does not exclude a carcinoma low down in the cervical canal it becomes obvious that vital staining is not as valuable a method of investigation as appears at first sight. Indeed we have come to the conclusion after careful trial of the method that visual and manual examination supplemented in difficult or doubtful cases by a wet film is the most likely to give an accurate picture of the various conditions we have treated.

Wet films are of use in this type of work because it is possible to give a diagnosis in the Out Patient Department while the patient waits, 10 minutes is all that is required in an urgent case, and because experience of this technique which has been in use at St Thomas's Hospital during the last 8 years has convinced us that in the hands of those who have studied the question the interpretation of films is accurate and reliable their preparation is simple, and the materials required are

available in any pathological laboratory. The reader is referred to papers (2, 3, 7) which have been published on this subject for they will serve as a guide to the technique of preparing wet films and the descriptions of preparations made from pathological conditions of all kinds elsewhere in the body give an idea of the value and limitations of the method. We have made wet films from every case in our series and a definite diagnosis has always been possible even in those instances where the staining of the cervix by Lugol's solution has been difficult to interpret or even deceptive.

The tissue removed with the punch must be teased out upon the slide before it dries, for the appearance of the cells alters rapidly if the tissue be kept for any length of time and it is essential that saline, preservatives, or other fluids are not used as diagnosis is not possible if autolysis has occurred. Sometimes it is difficult to make a good film from these cases because the piece of tissue available is small and may be very fibrous the best results are obtained by fixing it on the slide with a mounted needle and then teasing it with a scalpel which should have a broad blade. If the method is used in conjunction with Schiller's technique, as we have done it will be found that the epithelium which has taken the vital stain is decolonized at once by the Schaudinn's solution and consequently the iodine does not affect the subsequent staining with haemalum and eosin.

In order to interpret wet films made from the cervix it is necessary to have a knowledge of the normal histology of the part and the changes to which the cells are liable in health and disease.

In the normal cervix the junction of the squamous and the columnar epithelia is sharply defined and lies at the margin of the external os. The columnar cells vary in number and appearance not only with the age of the patient but also according to the stage of the menstrual cycle. It is usual to find them distended with mucus in vacuoles this can be confirmed by staining with muci-carmin. On the surface the epithelium is more regular and less distorted with globules of secretion than in the deep glands, and in old age the number of cells is diminished and the glands may be

Fig 3. Carcinoma of cervix. The plaque of epithelial cells in this film shows irregularity in the size and shape of the nuclei, an absence of cell membranes between the individual cells, and a tendency of the nuclei to separate from each other. Compare this film with Figure 1. $\times 280$

Fig 4. Carcinoma of cervix. The malignant cells are completely separated from each other. The nuclei vary enormously in size and shape. There are some mitotic figures and there is evidence of diffuse polymorphonuclear inflammation. $\times 280$

absent. The squamous epithelium of the adult is similar to that elsewhere in the body consisting of a basal layer, a zone of prickly cells and a mass of desquamating cells on the surface. In films the granules of glycogen cannot be seen, but in sections fixed in absolute alcohol and stained by Best's technique they are found easily and are scarlet. They are concentrated for the most part in the deeper layers of the epithelium.

The height and depth of the squamous epithelium vary in health and are not necessarily connected with pathological conditions; they bear a close relationship to the glycogen the cells contain, and this is dependent upon ovarian activity.

The epithelial cells rest upon a stroma composed of spindle cells and small blood vessels.

In films the various epithelial elements and the stroma are seen and the differences which occur in the normal cervix must not be forgotten.

The columnar cells in the film are found either in plaques resembling a tessellated pavement, or as a typical row of epithelial cells with an even round nucleus at the base of each cell. The mucus in these cells causes

variation in their size and shape but the regularity of the nuclei and the definite cell membrane are the features upon which the diagnosis of benign epithelium is made. Separation of the cells tends to occur if there is much mucus.

The squamous epithelium nearly always separates into two parts: the superficial desquamating cells break away in plaques from the prickly cells and basal layer and these plaques stain pink, whereas the deeper cells take up haemalum strongly and are blue. In the presence of acute inflammation it is not unusual for the squamous and columnar cells to be phagocytic and we have several films showing these cells engulfing polymorphonuclear cells. If this occurs the cells are much larger than normal, but the enlargement is confined to the cytoplasm and the nuclei remain small and regular.

The stroma is represented by groups of fibroblasts and by isolated spindle cells. In cases of cervicitis there are areas of granulation tissue and polymorphonuclear leucocytes are plentiful. It is occasionally possible to demonstrate capillaries in films made from granulation tissue.

The main application of this method is to distinguish between inflammatory and neoplastic conditions. We have noticed that almost every cervix we have examined has shown a marked degree of polymorphonuclear infiltration. This inflammation does not necessarily produce pain or symptoms, but is probably a cause of the excess of mucus secretion in chronic cervicitis. We have found inflammation not only in cases in which surface ulceration is present but in patients with an intact epithellum covering the cervix.

A diagnosis of carcinoma is made upon the appearance of the malignant cells themselves and does not depend upon infiltration of the neighboring tissues or the presence of metastases. The points upon which this diagnosis is made have been described fully elsewhere and the reader is referred particularly to the most recent paper on the subject in the *British Journal of Surgery* (2).

In recommending wet films as an aid to the diagnosis of lesions of the cervix, we desire to thank Professor Dudgeon who with C. V. Patrick introduced this method in 1927 and has helped us by examining the majority of the films we have made.

STUDIES ON PERIPHERAL VASCULAR PHENOMENA

IV FINGER VOLUME CHANGES IN A PATIENT SHOWING RAYNAUD'S PHENOMENA

CARL A JOHNSON M D AND ROBERT N HEDGES, M D CHICAGO ILLINOIS
 From the Departments of Medicine and Physiology of Northwestern University and St. Luke's Hospital

EVER since Raynaud (5) described the clinical entity carrying his name, this disease has been the subject of a great deal of study.

We wish to present a case upon which special studies were made that may throw more light upon the basis of the peripheral vascular phenomena which occur in this obscure disease.

REPORT OF CASE

Mrs I, 37 years old, consulted one of us (Hedges) in November 1933 for stiffness of the fingers. Her chief complaints were inability to play the piano and some pain and stiffness of the toes, when she walked. Mrs I states she had iritis of right eye in 1929 and following this her right ankle and wrist became swollen and tender. A diagnosis of arthritis was made and she had some teeth removed and a tonsillectomy performed. The arthritis subsided but she soon began to experience some stiffness of the fingers of both hands. No attention was paid to this condition until about April, 1933 when Mrs I was forced to stop playing the piano.

Previous to the above history patient had enjoyed good health. Her husband died suddenly in 1933 of septicemia. The family history was negative. There was no history of malaria. Physical examination is briefly as follows: height 5 feet, 6 inches; weight 147 pounds; blood pressure—right arm 110/68; left arm 94/68; pulse 88.

Color of both hands was poor—dusky color. The skin was tense over the fingers, especially of the right hand. The first and second fingers of right hand were stubby but did not show a true clubbing. The hands were cold. She was unable to flex the fingers of either hand, especially the right hand. There was no muscular atrophy of the arms. The hands appeared small and perspired freely in palms. Some slight nutritional disturbance of finger nails was present. Pain was present across the knuckles when hand was pressed. There was a thickening of the skin of the ventral surface of the hands. There was a definite line of demarcation just distal to the middle joint of the fingers of both hands on immersion in cold water. This pallor remained for about 3 minutes and was replaced by cyanosis (Fig. 1). There was no disassociation of heat and cold sense on either arm or hand.

The lower extremities were practically normal although there was some slight enlargement of the

joints present. The blood was normal with the exception of a slight anemia—3,900,000 red blood cells. The urine was negative, no Bence Jones protein present. Blood chemistry analysis: normal calcium 9 milligrams per cent; phosphorus, 2.8 milligrams per cent. The blood viscosity was normal. The electrocardiogram was normal.

Roentgenograms were made of both hands (Fig. 2).

One showed considerable loss of distal phalanges especially of the right hand.

Roentgenograms of the feet showed no such destruction of bone. There was no cervical rib present and X-ray examination of the long bones, head and pelvis showed no systemic bone involvement.

Studies on the peripheral circulation were made with a special device previously described by Johnson. This device measures the finger volume change associated with the heart beat. Skin temperature changes were made with the ordinary thermocouple and color changes were observed by comparison with the color charts as devised by Lewis.

The finger volume changes at room temperature were uniformly lower than usually observed in the normal human being. Also the skin temperature was uniformly lower than observed in the normal (Figs. 3, 4, 5).

Immersion of the hands in hot water (45 degrees C for 10 minutes) caused a moderate increase in the finger volume changes (Fig. 3).

Immersion of the hands in cold water (10 degrees C) caused a reactive hyperemia associated with increased finger volume changes without cyanosis.

Occasionally it was possible to induce a spasm of the peripheral vessels by immersion of the hand in moderately cold water (between 13 degrees and 18 degrees C). Associated with this the fingers assumed the color changes characteristic of Raynaud's phenomenon. This is in keeping with the observations of Lewis, that the optimum temperatures for inducing a spasm lie between 13 and 18 degrees C.

The color changes of Raynaud's phenomenon were most easily induced by having the patient go out of doors and expose her hands to moderately cold air and Figure 4 shows graphically the changes which occur during the spasm. It is shown by these charts that even in the very cyanotic stage the finger volume changes were greater than the control and subsided to a very low level in about an hour. As will be seen from the charts the skin temperature did not bear uniform relationship to the color changes or the finger volume changes in this particular case.

Fig. Photograph of the patient's hands during an attack. Note the cyanosis of the fingers of the right hand up to the first interphalangeal joints. The ends of the fingers are stubby but a true chelbing is not present. This is particularly true in the right hand where the absorption of the terminal phalanges is most marked (see Fig. 2).

Fig. 2. Roentgenograms of the bones of both hands showing the absorption of some of the terminal phalanges. This is most marked on the right.

Treatment. This patient was given tissue extract because it was supposed to cause vasodilatation, but it has been shown by Roth and Barber not to exert its effect by vasodilatation. These authors think that its action is directly on the muscles supplying a deficiency due to inadequate blood flow.

The result was not very satisfactory in this case, although, if a spasm was induced by exposing the hands to cold air, tissue extract would cause a color change, i.e. from cyanosis to a more normal color.

After several months treatment with tissue ex-

tract, Mrs. I. noticed improvement in her ability to move the hands. No noticeable improvement was noted in the scleroderma. The vascular spasms were of about the same intensity at the termination of treatment and about the same duration. The tissue extract would cause a color change lasting about 2 hours. Figure 5 shows the results upon the skin temperature, color and peripheral pulse volume. There was improvement in the colors of the fingers of the right hand but no increase in the pulse volume changes. From this result it would be difficult to

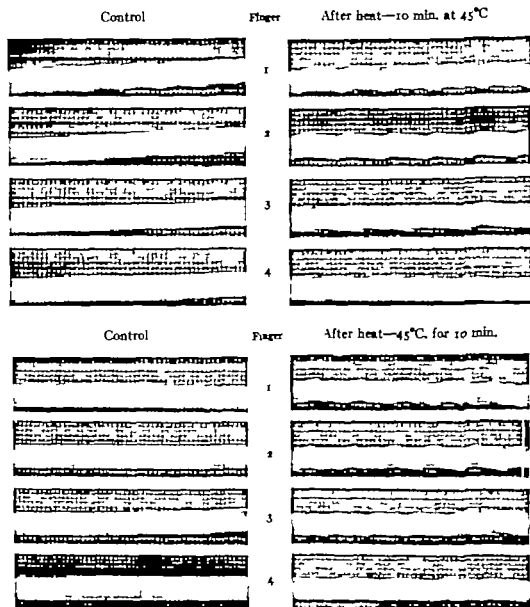

Fig. 3 The finger volume changes of the fingers before and after the application of local heat. (Immersion of the hand in water at 45 degrees C for 10 minutes). The upper record shows records from the fingers of the right hand and the lower are the left. Note the very low amplitude in the control records indicating that under normal environmental conditions the circulation is less than normal. The local heat relaxes the peripheral vessels and allows for an improved circulation.

draw any conclusions regarding the value of this medication.¹

The classification of this case as one of Raynaud's disease is open to some question because as Lewis states 'Thus it is quite possible that patients who in the first instance display attacks of cyanotic fingers and subsequently acquire a general scleroderma are essentially of the same type, but as we have yet

¹Later experiments have shown that it is possible to demonstrate a vasodilatation, as evidenced by increased finger volume changes, by using larger doses of lumps extract and waiting a longer period. The maximum change occurs in about 34 hour and the effect wears off in about 1 to 2 hours, depending upon the dose.

no proof that the vessels in these cases respond directly and unusually to temperature and as we do not understand how the general scleroderma occurs it is quite clearly desirable that this class of case should be kept apart until it has been submitted to suitable investigation' (4). On the other hand, we think this case would fall into group 2 of the 204 cases of Raynaud's disease as reported by Allen and Brown (1). Kolodny (3) reported a case with symptoms and X ray findings similar to the one we have described who received con

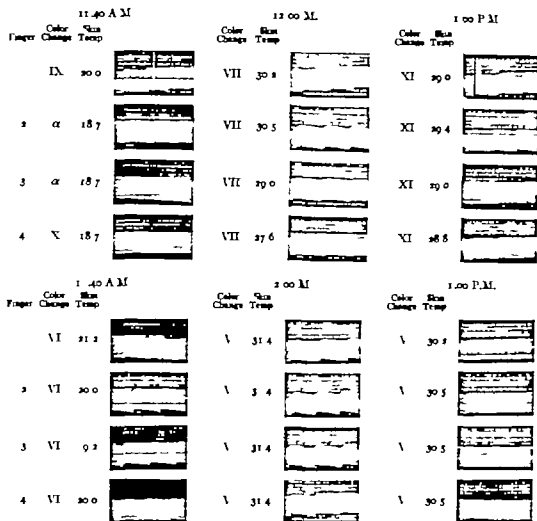

Fig. 4. The finger volume changes in the fingers of both hands just following vascular spasm. The upper record as the right side and the lower the left. The skin temperatures are shown and the Roman numerals and letters represent the colors of the fingers as compared with the color charts devised by Lewis. Note that in the cyanotic stage the fingers become warm and the pulse volume changes are increased indicating an increased circulation. This subsides in about an hour to a very low level, but the skin temperature changes lag considerably behind this change.

siderable relief from a cervical ganglionectomy and ramisection. We consider our case one of Raynaud's disease complicated with scleroderma and sclerodactylia.

The symptoms in our patient are quite characteristic of Raynaud's disease.

There is a long history of rather painless attacks of cyanosis of the fingers up to the first interphalangeal joints (Fig. 1). The disease is symmetrical, i.e., it involves the fingers of both hands and also less severely the toes of both feet. The attacks are initiated most

easily by moderate cold such as temperatures between 13 and 18 degrees C. An attack is more easily initiated by exposure to cool air than by immersion of the hand in cold water. As was the case with most of Lewis's patients the phenomena of pallor did not occur but the fingers became cyanotic or violet and as recovery took place became red and finally assumed their usual color.

The plethysmographic studies lend support to the diagnosis of Raynaud's disease. The pulse volume tracings in the absence of an

attack were uniformly lower than in normal individuals indicating a large vasospastic element (Figs 3, 4, 5). This could be relieved by immersion of the hand in hot water (Fig. 3). When an attack occurred and the blue color appeared the skin temperature rose rapidly and the pulse volume changes increased. As the attack subsided the pulse volume changes decreased to a subnormal level but the skin temperature did not parallel these.

Operation with a cervical ganglionectomy and ramisectomy was advised, but the patient refused. It was felt that the interference with the heat regulating mechanism of the upper

extremities as evidenced by the increased skin temperatures following this operation would render her less liable to attacks.

SUMMARY AND CONCLUSIONS

We have presented a case of Raynaud's disease complicated with scleroderma and sclerodactylia.

Circulatory studies were made with a special finger plethysmograph which indicate that in this case the peripheral circulatory changes were as follows:

1 The circulation was persistently less than normal in the fingers even in the absence of an attack.

2 A peripheral vasodilatation could be induced with local heat.

3 During the cyanotic stage of Raynaud's phenomenon the circulation was increased

4 Tissue extract improved the color of the fingers, but did not induce vasodilatation

ELECTROSURGICAL ASEPTIC INTESTINAL ANASTOMOSIS¹

ROBERT P WADHAMS, M.D. F.A.C.S. and VICTOR CARABBA, M.D. F.A.C.S. NEW YORK, NEW YORK

ELECTROSURGICAL methods as applied to the hollow viscera are still in the experimental and very early practical clinical stages and further studies are imperative before their actual value can be established. With this in mind we have performed several different types of aseptic intestinal anastomosis experimentally and have applied the procedure clinically in man.

This paper is a presentation of the experimental technique used the surgical pathologic physiology of the procedures and the suggestions of their clinical application in man.

Ward (2) at Kelly's suggestion performed anastomosis by electrocoagulation as follows:

The loops to be joined were grasped with the usual anastomosis clamps drawn together parallel. Two layers of Lambert suture were used to approximate the posterior walls of the proposed stoma. In lieu of making an opening into the lumen of the loops, the intended sites of opening were coagulated by inserting a needle electrode carrying a biterminal current down to but not through the mucosa, relying on the coagulation at the tip of the needle to destroy the mucosa also. The needle not piercing the mucosa, obviated any immediate contamination from the bowel lumen. The two anterior layers of sutures were then laid, completing the operation. In from 24 to 48 hours, the coagulated tissue sloughed through and completed the anastomosis. The technique was fairly satisfactory in the intestinal anastomosis but was not to be relied upon in the stomach with its redundant mucosa which was coagulated ineffectually. We have not yet tried this procedure on man and feel that it is not applicable where there is an immediate need of an anastomosis.

Briggs (J E) and Whitaker (L R) later reported similar experiments performed independently of Ward's. Their technique calls for only one row of sutures to avoid leakage, as the delayed opening

allows thorough sealing of the edges of the anastomosis by the fibrinous exudate before there is any chance for contamination.

In an effort to perfect an aseptic anastomosis technique that would immediately open the loops at operation, W W Walker devised a small hollow wooden instrument (Fig. 158) about the diameter of a lead pencil and 2 inches long. A groove was cut on each side, through which two pointed prongs could move from one end to the other by means of a stiff wire extending out of the end of the instrument. At operation, the posterior sutures were laid first, the instrument being placed between the loops so that the sharp prongs would each pierce the wall of one loop. The anterior sutures then closed the loops over the instrument. As a biterminal current was applied to the wire projecting from the end of the instrument, traction was made, drawing the prongs through the walls and cutting the tissues as they passed. On removing the instrument, the incisions were found to be open and dry, all vessels having been coagulated. The impractical feature of this instrument lies in the inability to remove it from between the loops of bowel in a completely aseptic fashion as at present constructed, it must be withdrawn from its position into the sterile field. At attempts have been made to obtain an insulating substance out of which a collapsible instrument could be constructed, which would fall within the lumen of the intestines and later be passed. The material out of which such an instrument is made must of necessity be sterilizable and capable of being worked up into a tiny device. These obstacles are technical and are being studied.

The following operations have been successfully performed by us experimentally: (1) gastro-enterostomy (2) cholecystgastrostomy (3) anastomosis of small intestine to small intestine (4) anastomosis of small intestine to large intestine (5) anastomosis of large intestine to large intestine (6) anastomosis of ureters to large intestine. On man we have

successfully performed a side-to-side anastomosis in the large bowel

APPARATUS AND INSTRUMENTS

Any inexpensive apparatus carrying coagulating current which can be set to 1000 milliamperes and ranging to 1500 milliamperes can be used. We have employed an ordinary commercial model carrying the above range of coagulating current. To set the apparatus the milliammeter is connected to the diathermy pole and the spark gap advanced until the milliammeter registers 1000 milliamperes. The degree of spark gap advancement necessary to raise the coagulating current to 1500 milliamperes is then noted. The diathermy connection is transferred to the coagulation pole and the other connected to the indifferent electrode. Since 1000 milliamperes is the amount of current of choice the spark gap is reduced to that point in the apparatus.

This amount of current gives a slow even and penetrating coagulation without causing distant injury and avoids loss of control. The coagulated tissue first turns white 'parboiled' about the same color as the coagulated albumin of a hard boiled egg. If coagulation is continued further the 'parboiled' area turns a light grey, then a dark grey followed by charring. In ordinary work on the small and large bowel the light grey color is the optimum stage of coagulation. In doing work on thicker viscera as the pylorus and stomach a little darker grey is the optimum stage of coagulation. Therefore one can regulate quantitatively by increasing the milliamperage, the speed, and degree of coagulation.

The electrodes are the unipolar (Fig 1a) the bipolar (Fig 1b) and the multipolar (Fig 1c). The unipolar electrode consists of an ordinary non-cutting intestinal needle affixed to a holder and used in conjunction with an indifferent electrode which is placed under the patient to complete the circuit. While this electrode can be used for any type of work it is slow and tedious when long lines of coagulation are to be made. Therefore it is reserved for fine point coagulation as in performing operations on the gall bladder and ureters.

The bipolar electrode (Fig 1b) is the electrode used for electrocoagulation of tonsils

Fig 1: Electrodes a, Unipolar b, bipolar c multipolar

and sold commercially for that purpose. The points of the electrode are introduced through the serosa and embedded in the muscularis of the portion of the intestine to be coagulated and gives an area of coagulation 5 millimeters in circumference and through all the layers of the bowel. In doing work on the stomach or pylorus the needle points must be introduced deep into the muscularis to insure coagulation of the mucosa. One can readily see that by point-to-point coagulation linear circular etc. coagulation can be fashioned.

The multipolar electrode (Fig 1c) was devised by one of us and constructed at the university machine shop. It is in reality a six pronged bipolar electrode giving a line of coagulation 2.5 centimeters in length and through all the layers of the bowel. The same technique is employed as in the use of the bipolar electrode. Long lines of coagulation can be performed very quickly thus greatly reducing the time of the procedures.

TECHNIQUE

The general principle of the operation for aseptic intestinal anastomosis is illustrated in Figure 2. The loops to be anastomosed are approximated by a seroserous continuous suture of 20 day chromic No. 00 atraumatic, as is done in the first step of any conventional type of anastomosis (Fig 2a). With the bipolar or multipolar electrode two lines of coagulation are performed on what normally would be the lines of cautery incision in the conventional technique. The multipolar electrode is the instrument of choice attached to 1000 milliamperes coagulation current. The prongs are introduced through the serosa and into the muscularis. The coagulating points

Fig. 1. Enterocolostomy. a, Seroseros cotuberos suture. b, lines of coagulation. c, approximation of lines of coagulation. d, completion of seroseros suture. e, external appearance of healed anastomosis. f, stoma of anastomosis perfectly formed and healed.

must enter 1 centimeter away from the seroseros suture line and must begin and end $1\frac{1}{4}$ centimeters proximal to the ends of the seroseros line of suture (Fig. 2b). The circuit is completed by means of a foot switch controlled by the operator. The area around the electrode gradually turns white, parboiled and becomes as hard as shoe leather and then turns light grey. When the white parboiled color appears, the area is carefully watched as it quickly turns to a light grey which represents the optimum point of coagulation. The foot switch is then released and the electrode advanced further to a new segment of the coagulation line until the two lines of coagulation are completed as shown in Figure 2b.

The two lines of coagulation are approximated by a series of two or more Lembert sutures of plain catgut as shown in Figure 2c placed $1\frac{1}{4}$ centimeters apart. The seroseros suture begun in step 1 (Fig. 2a) is now com-

pleted to bury the two apposed lines of coagulation (Fig. 2d).

In the first 24 hours there is an inflammatory reaction which completely seals the area between the lines of coagulation and the seroseros suture. When the suture begins to separate at the end of the 24 hour period no spillage can take place into the peritoneal cavity. Gas and liquid usually pass through in 36 hours and within 48 hours the anastomosis allows also solids to pass. In 7 days the anastomosis is completely formed and healed.

The animal made an uneventful recovery and the specimen obtained showed the complete external healing (Fig. 2e) and perfectly formed and healed anastomosis (Fig. 2f). It is of interest to note that this represents a successful anastomosis between the third portion of the duodenum and the ascending colon. These two loops were chosen because the anastomosis of these two loops represents the

healed external appearance of enter-enterostomy following intestinal resection d stoma healed and functioning

severest test that can be given any technique for anastomosis. Three controls in which the conventional suture methods were employed and the most scrupulous asepsis and technique were used all promptly died with infection and secondary leakage. One must remember the strong digestive power of the duodenal contents and the virulence of the faecal material to understand readily the poor results that are obtained by the use of the conventional method.

The final length of the completed anastomosis is usually two-thirds the length of the original line of coagulation. If a 2 inch anastomosis is desired as a final result the line of coagulation must be 3 inches in length. No special aseptic precautions are necessary; there is no spilling, no haemorrhage and the time for the operation is one third the amount used in doing the conventional type of operation.

Anastomosis of jejunum to ileum 2 weeks after operation is shown in Figure 3. This technique is most adaptable and successful in this type of anastomosis. Figure 3a demonstrates the perfectly healed serous surfaces and Figure 3b the perfectly formed healed and functioning anastomosis. As in all our experiments no pre-operative or postoperative special precautions as to diet etc. were taken in order to give the technique a severe test.

INTESTINAL RESECTION AND SIDE TO-SIDE ANASTOMOSIS

Twelve inches of ileum were resected and the ends of the resected bowel were inverted in the usual way. A side-to-side anastomosis was performed as shown in Figure 2. The dog never refused food and never had any symp-

toms or signs of intestinal obstruction. Four weeks after operation the dog was sacrificed and the perfectly formed and functioning anastomosis is shown in Figures 2 3c, and 3d

GASTRO-ENTEROSTOMY

The electrosurgical technique for this operation is identical to that for side to side anastomosis of the bowel. The multipolar elec

Fig 8. Gross surgical pathology. a, Twenty-four hour appearance of stomach, with slough ready to separate. b, 48 hours slough separated. c, slough completely separated with early healing of mucosa.

trode is used with its prongs inserted deep into the muscularis of the stomach and 1500 milliampere current is used. The line of coagulation must be grey in color. In performing the line of coagulation on the loop of small intestine 1000 milliampere current is used and the electrodes inserted as described in the previous operation.

The illustrations Figure 4 represent the results 10 days after operation of a gastrojejunostomy as performed on the dog. The dog was allowed the usual rations and purposely no special postoperative care was taken in order to give the operation the severest test possible. The animal made an uneventful recovery and did not miss a single meal.

Figure 4a represents the external appearance of the healed anastomosis and 4b the anastomosis opening perfectly formed functioning and well healed.

We do not agree with Ward that the redundant mucous membrane of the stomach prevents the use of this technique. Failure to coagulate the mucosa properly is only a technical one and if the electrode is introduced as directed and coagulation done to a grey color with 1500 milliampere current the mucous membrane will be properly coagulated.

This technique is not suggested to supplant the present technique by suture method. The operation has a place however when in repairing a ruptured duodenal ulcer a gastroenterostomy is necessary. If suturing the ulcer causes a too marked stricture and a gastroenterostomy is necessary, this technique should be used. The procedure is quick

ly done and does not expose the patient to spilling hæmorrhage or prolonged surgical technique. The anastomosis forms itself automatically while the ulcer surface is healing.

Fig 9. Microscopic surgical pathology. a, Twenty-four hours postoperatively, slough still attached. b, 48 hours after operation, slough almost entirely separated. c, 8 days after operation, mucosa entirely joined and healed.

ENTERO-ENTEROSTOMY OF LARGE BOWEL TO LARGE BOWEL

A 6 inch loop of descending colon was sutured together near the mesenteric attachment by a continuous seroserosus suture of 20 day No 00 chromic (Fig 5a). Two lines of coagulation with 1000 milliampere current and multipolar electrode were fashioned on each of the opposed loops as shown in Figure 5b. The lines of coagulation were opposed and sutured together by eight interrupted Lembert sutures of plain catgut No 0 as shown in Figure 5c. The seroserosus suture (Fig 5d) was then completed thus burying the line of coagulation. The colostomy was then sutured to the pentoneum and allowed to protrude from the skin wound. The summit of the colostomy was coagulated at one point with the bipolar electrode (Fig 5f) so that in 36 hours it opened spontaneously. After 48 hours the colostomy functioned perfectly externally and internally. On introduction of a finger the anastomosis was found to be perfectly functioning. The dog moved his bowels both by rectum and through the colostomy. Figure 5g represents the internal view of the anastomosis perfectly formed and healed. Figure 5h shows the functioning opening of the colostomy on the abdominal surface.

Every surgeon knows the scrupulous asepsis necessary not only in performing anastomosis of the large bowel on the human, but also in animals. The danger of infection, leakage, and peritonitis in the face of the virulent flora is very great. The procedure as above described is perfectly adequate and safe and eliminates the difficulty of maintaining asepsis since the bowel is not opened.

This type of colostomy and anastomosis suggests two new uses. The first is a large pouch colostomy. Instead of the centripetal loop only emptying itself as in the conventional colostomy, we have a large reservoir of both loops. The centrifugal loop is turned into a centripetal loop. The large pouch allows of less frequent movement of the bowel and might afford more cleanliness and comfort to the patient.

The second use is the performing of what normally is the second stage of a Mickulicz operation in the first stage of that procedure.

By the time the external colostomy is opened after the excision of the tumor, the internal anastomosis is already formed and functioning. This obviates the secondary clamping which is tedious and oftentimes difficult and unsatisfactory. We have performed such a procedure on the human with much success and gratification.

CASE REPORT

I L aged 56 years was admitted to Bellevue Hospital May 24, 1934, with a history of bloody stools, diarrhoea and pain in the left iliac region since January 1934. After a careful study including X rays a definite diagnosis of carcinoma of sigmoid at its junction with the descending colon was made.

At operation the mass was found and a Mickulicz operation done. A 4 inch side to-side anastomosis by electrocoagulation was performed just proximal to the mass as shown in Figure 5. Two days after operation a finger introduced through the colostomy opening revealed the anastomosis already formed and functioning. On the third day the patient had several small bowel movements by rectum and by the fourth day copious bowel movements.

In September 1934 she returned to clinic and examination revealed a healed colostomy wound and a perfectly functioning sigmoid with normal daily bowel movements and a gain of 25 pounds in weight.

CHOLECYSTGASTROSTOMY

In performing cholecystgastrostomy by electrocoagulation the pylorus was selected for the anastomosis. As the pylorus is extremely thick in the dog it offered an excellent test for the procedure.

The fundus of the gall bladder was sutured to the serosa of the pylorus transversely to its axis. Five millimeters away from this suture line and at its center the gall bladder was coagulated at one single point with the bipolar electrode piercing only the serosa. The 1000 milliampere current was used and the coagulation continued to a light grey color and 5 millimeters in circumference. At a point in the pylorus directly opposite to the point of coagulation on the gall bladder a 5 millimeter point of coagulation was performed. The bipolar electrode was used, introduced well through the muscularis. The coagulation was performed to a grey color and 1500 milliampere current was used. The areas of coagulation were opposed by two interrupted sutures of 20 day No 00 chromic catgut.

Fig 8 Gross surgical pathology a, Twenty-four hour appearance of stoma, with slough ready to separate b, 45 hours slough separated, c, slough completely separated with early healing of mucosa

trode is used with its prongs inserted deep into the muscularis of the stomach and 1500 milliamperes current is used. The line of coagulation must be grey in color. In performing the line of coagulation on the loop of small intestine 1000 milliamperes current is used and the electrodes inserted, as described in the previous operation.

The illustrations Figure 4 represent the results 10 days after operation of a gastrojejunostomy as performed on the dog. The dog was allowed the usual rations and purposely no special postoperative care was taken in order to give the operation the severest test possible. The animal made an uneventful recovery and did not miss a single meal.

Figure 4a represents the external appearance of the healed anastomosis and 4b the anastomosis opening perfectly formed functioning and well healed.

We do not agree with Ward that the redundant mucous membrane of the stomach prevents the use of this technique. Failure to coagulate the mucosa properly is only a technical one and if the electrode is introduced as directed and coagulation done to a grey color with 1500 milliamperes current, the mucous membrane will be properly coagulated.

This technique is not suggested to supplant the present technique by suture method. The operation has a place, however when in repairing a ruptured duodenal ulcer a gastroenterostomy is necessary. If suturing the ulcer causes a too marked stricture and a gastro-enterostomy is necessary this technique should be used. The procedure is quick

ly done and does not expose the patient to spilling hemorrhage, or prolonged surgical technique. The anastomosis forms itself automatically while the ulcer surface is healing.

Fig 9 Microscopic surgical pathology a, Twenty-four hours postoperatively, slough still attached, b, 45 hours after operation, slough almost entirely separated, c, 6 days after operation, mucosa entirely joined and healed

in place except at certain points in the periphery where gas and liquid material could filter through. Slight traction on the slough easily separates it from the points of attachment.

The hemorrhagic ring about the points of exit and entrance of the sutures in the serosa is rapidly disappearing in the 48 hour specimen. On division of the sutures and application of tension on the agglutinated seroserosus surfaces, it was found that they could still be separated but with much difficulty. No leakage could possibly occur at this stage of the healing process. The slough (Fig 8b) has completely separated with the exception of a few strands along the now perfectly formed and functioning anastomosis.

In 72 hours (Fig 8c) the slough has completely separated even along the edges of the anastomotic opening and is being replaced by healthy granulation tissue.

The 8 day gross specimen reveals the mucous membrane in the anastomotic opening completely healed over.

Microscopically the 24 hour specimen shows the slough with the picture of coagulation necrosis (Fig 9a A). The slough is definitely still adherent but separating in places. The agglutinated seroserosus surfaces (Fig 9a, B) demonstrates the rather air tight union of these two surfaces. The 48 hour microscopic section (Fig 9b) demonstrates the separation of the slough, A. Along the periphery there are still some adherent strands of slough. The area of coagulation necrosis is definitely demarcated from the healthy intestinal wall. In 72 hours the remaining slough is completely separated.

In 8 days the mucosa is completely regenerated and healed from one side of the anastomotic opening to the other (Fig 9c A).

EVALUATION

We do not agree with Ward (2) that the electrocoagulation procedure cannot be relied upon on the stomach with its redundant mucosa. The failure is purely one of lack of properly performing the electrosurgical technique especially as to the depth and strength of the current and the degree of coagulation.

The technique of J. E. Briggs and L. R.

Whitaker, calling for only one row of sutures in our experience is adequate.

The attempt of W. W. Walker to perfect an aseptic anastomosis technique that would immediately open the loops at operation to our mind has no relation to the technique as it is described by J. F. Briggs, Ward or ourselves.

In retrospect there are only extremely rare instances in which immediate anastomoses are necessary. In cases in which immediate intestinal drainage is necessary temporary ileostomy, colostomy or appendicostomy can be performed. In cases of intestinal resection the anastomosis can be performed below the lumen of the resected bowel and the lumen allowed to drain externally while the anastomosis forms and begins to function.

The question most frequently asked is 'How does one know that the anastomosis will always form?' If the procedure is carried out as described, the anastomosis will always form. In a long series we never failed even in our early experience with this method.

Secondary hemorrhage is feared by many. We have never seen a case of secondary hemorrhage in 15 consecutive operations by this method. All the animals were carefully watched after operation and at autopsy for this complication.

POSSIBLE APPLICATIONS TO THE HUMAN

1. Gastro-enterostomy—by electrocoagulation when a such procedure is necessary in repairing a perforated duodenal ulcer complicated by stricture.

2. Lateral anastomosis after resection of segments of the bowel secondary to partial gangrene of a portion of the bowel as in strangulated Richter's hernia, gangrene due to bands femoral hernia etc. The two open ends of the loop left externally for drainage until the obstruction is relieved. The fistula can be then allowed to close spontaneously or repaired secondarily. This same procedure can be applied in performing an entero-colostomy.

3. A. Ileosigmoidostomy as a preliminary procedure to resection of the caecum.

B. Ileosigmoidostomy of choice with a temporary colostomy or appendicostomy.

4. Mickulicz operation completed in the first stage of the operation eliminating the secondary clamping

5. Cholecystgastrostomy or enterostomy

6. Anastomosis of ureters to large bowel

7. Without obstruction primary resection of large intestine with side-to-side anastomosis instead of the Mickulicz operation

SUMMARY AND CONCLUSIONS

Fifteen consecutive and diversified anastomoses as performed on the dog and one as

performed on man were successfully performed by electrocoagulation technique without mortality leakage infection or hemorrhage

The procedure might in the future represent another step forward in surgical advancement.

We are deeply indebted to Dr. Leona McCloskey for her valuable assistance in the conduct of this work.

THE ACTIVITY OF HAIR FOLLICLES WITH REFERENCE TO PREGNANCY

MILDRED TROTTER, Ph.D. ST. LOUIS, MISSOURI
Department of Anatomy Washington University School of Medicine

THE condition of pregnancy is believed by many to influence hair growth in given regions of the body. However there is no unanimity of opinion either as to the question whether growth is retarded or accelerated or with reference as to which areas are affected. Diverse observations have been made both on man and on some of the lower mammals.

As early as 1875 Slocum reported the case of a woman in whom hypertrichosis developed during each of three pregnancies, and *post partum* the hypertrichosis disappeared. Halban (1906) found quite regularly an increased growth of hair on the face of pregnant women but this growth was more marked when the tendency toward hypertrichosis was already present. He also mentions an increased growth of lanugo hair over the whole body and especially in the region of the linea alba between the umbilicus and the pubic region. In each instance there was a return to normal *post partum*. In 1913 Harabath concluded that increased hair growth appears so regularly and typically in pregnant women that its appearance may be listed under the external symptoms of pregnancy. Many citations of cases of increased hair growth during pregnancy may be found in the literature but there are also some cases reported of retarded

hair growth coincidental with the period of gestation (Bechet 1921 Ochs, 1928). These observations on women have been made for the most part by physicians who saw them as patients and had their attention called to the altered hair growth by the patient. In other words, the individuals were a selected group.

The reports on animals are of quite a different character however. In that experiments were planned and carried out on unselected groups in which were included control series Halban (1907) shaved the abdomen of female rabbits in a group half of which were pregnant. The hair regenerated much more quickly on the pregnant ones than on the control group. Harabath (1913) observed hypertrichosis in three pregnant dogs especially marked over the abdomen and to a less extent over the whole body. On the other hand Dawson (1933) found a marked retardation of hair growth in pregnant guinea pigs particularly over the back, normal growth rate being restored *post partum*. Strangeways, later in the same year (1933) also observed these phenomena in guinea pigs.

Thus it appears that pregnancy retards hair growth in some species of the lower mammals and accelerates it in others. There is evidence that both effects are produced in man. The observations reported in this paper were made

in order to ascertain the effect of pregnancy on hair growth in certain selected regions of a group of unselected women

Seven women, whose co-operation was obtained through the obstetrical clinic of Washington University, permitted weekly examinations for a period of approximately 9 months. The period was divided in each case into two parts by the birth of the child—thus the examinations were made during the latter part of the pregnant period and for several months following delivery. The subjects, their ages, the number of the pregnancy in each case, and the lengths of the periods before and after delivery are shown in Table I

TABLE I

Subject	Age (years)	Pregnancy	Weeks before delivery	Weeks after delivery
B	30	First	5	14
F	26	First	17	20
G	30	Second	13	14
M	24	First	5	5
Sa	26	Third	17	17
Bc	30	First	25	13
St	24	Second	25	8

The average length of the period over which each woman was examined was 36 weeks, 21 weeks before delivery and 15 weeks after delivery

The color of the head hair was medium or dark brown in each case except that of M whose hair was red. The pubic perineal and lumbar regions were chosen for observation. The terminal hair of the pubic and perineal regions appears and acquires its distinguishing characteristics during puberty and is thus probably influenced by the changes occurring in the reproductive system at this time as much as if not more than hair on any other part of the body. (The axillary hair of course is in the same category as the hair of the pubic and perineal regions but was not chosen for the experiment because of the quite prevalent custom of frequently shaving the arm pits). The lumbar region is covered with hair of the lanugo type which is typical of the general hairy covering of the body. In each region from ten to fifteen follicles were marked by in-

jecting a small amount of India ink under the skin on either side of the follicle. These ink marks are permanent and therefore insure the identification of the follicle from week to week. Measurements of the hairs of the marked follicles were made weekly with a millimeter ruler

The behavior of the follicle is known to be cyclic in character, i.e., a period of hair growth followed by a quiescent period after which the hair falls out and the growth period of the next hair is begun (Trotter, 1924). Thus, the measurement of the hairs made at regular intervals provides information on the rate of growth, the length of the active (or growth) period and the length of the quiescent (or rest) period of the cycle through which the follicle passes and the ultimate length of the hair. Since all hairs in a given region are not in the same phase of the cycle at the same time, only part of the hairs at the time of the first measurement would be at the beginning of their growth period. The stage of the cycle of any individual hair was purely a matter of chance and not evident until after the second measurement. This resulted therefore, in not having in every case full information on the growth and quiescent periods of the same hair i.e., on the complete cycle of the follicle

The hospital routine includes shaving the pubic and perineal regions just before delivery and whereas this proved to be a slight inconvenience from the standpoint of the experiment no information was lost. The hairs in the growing phase of the cycle continued to grow and this length added to the length of the hair before shaving gave the ultimate length whereas those hairs in the resting phase of the cycle continued to remain quiescent and their cut ends which were on a level with the surface of the skin were plainly visible. The measurements on all the hairs in each region of each individual were averaged. The data are summarized in Table II

A comparison of the rate of weekly growth before and after delivery in each of the three regions shows a slightly higher growth rate in some before delivery and in others after delivery. In no individual is the difference a marked one. On the whole the tendency, although inappreciable and probably within the

range of error is for a somewhat faster rate of growth after delivery than before. There does appear however a tendency for the hair of the perineal region to grow faster than the hair of the pubic region and for the hair of the lumbar region to grow the most slowly. There was no difference in the number of growing hairs during pregnancy and after delivery.

TABLE II—AVERAGE MEASUREMENTS OF FOLLICULAR ACTIVITY IN THE PUBIC PERINEAL AND LUMBAR REGIONS OF SEVEN WOMEN

Subject	Rate of growth (mm per week) before delivery	Rate of growth (mm per week) after delivery	Growth period (weeks)	Rest period (weeks)	Ultimate length (mm)	
Pubic region	B	3	15	14	34	
	F	3	3	5	31	
	G		4	3	3	
	M	8	6	14	35	
	Sa	7	3	3	43	
	Sc	7	8	14	43	
Perineal region	S	5	6	13	33	
	B	8	7	10	7	
	F	3	8	3	19	33
	G	7	7	9	31	
	M	3	2.6	11	73	
	Sa	9		14	19	46
Lumbar region	Sc	7	6	3	19	39
	Sa	7	3	17		65
	B	9		6		19
	F	9	6	4	19	9
	G		3	9	7	
	M		7		9	
	Sa		3		19	
	Sc		4	19	3	
	St		4	6	3	

The length of the growth period and of the quiescent period of the follicle and the total length of the hair are recorded without reference to the termination of pregnancy; this was essential because of the limited time over which the experiment was carried. Nine months is a relatively long period when the patience and time of the subject is considered but a relatively short one when it is considered that a complete follicular cycle covers from 5 to 8 months. The growth period for the hair of the pubic and perineal regions is of

longer duration than the quiescent period, but in the lumbar region it is approximately only half as long as the quiescent period. The quiescent periods of follicles of the lumbar and perineal regions are about the same length, whereas the quiescent period of the follicles of the pubic region is somewhat longer.

The lengths of the hair in the three regions are also variable. The perineal region has hair which is only slightly longer than the hair of the pubic region but the hair of the lumbar region is very much shorter (approximately one fifth as long) than either of these. Thus, it appears that the shorter hair (lumbar) has a much longer quiescent period than growth period and that the longer hair (pubic and perineal) has a somewhat longer growth period than quiescent period—of these two regions the perineal hair is the longer with a definitely longer growth period than rest whereas the pubic hair which is not quite so long as the perineal has growth and quiescent periods of more nearly equal length. It may be noted also that the lengths of the individual growth periods of the pubic and perineal regions are approximately equal (exactly equal in the case of B, F and G) with the exception of M whose perineal hair grows for a much longer period than her pubic hair. The similarity in length of the growth periods of the two regions in the 6 individuals is further evidence that the excessive length of the hairs of the perineal region is due to a faster rate of growth. However the number of subjects is too small to warrant either stating an average for the group or calculating a correlation between two or more of the observations recorded.

It may be assumed that the rate of weekly growth times the length of the growth period which is given in weeks should indicate the exact total length of the hair. This does not always follow and the discrepancy is explained by the fact that the rate of growth data are compilations of partial cycles of follicular activity (the weekly rate of growth could be determined from measurements of length for only a few consecutive weeks of the growth period) also the ultimate length of the hair could be determined after the quiescent period was recognized which necessitated only a few

TROTTER ACTIVITY OF HAIR FOLLICLES WITH REFERENCE TO PREGNANCY 1095

weeks, whereas the length of the growth period could only be determined from follicles which had been observed from the time the hair appeared until the quiescent phase was established. Thus, many more hairs contributed information on rate of growth and on ultimate length of the hair than on the length of the growth or of the rest periods, both requiring observations throughout the entire period. The discrepancy, therefore, is the result of individual variation of the hairs.

The amount of hair in the regions under observation did not change perceptibly during the entire period of 9 months. Nor could any one of the subjects notice alteration in any part of the hairy covering of her body.

SUMMARY

Measurements on the rate of hair growth in the pubic, perineal, and lumbar regions of a group of seven women made during the latter months of pregnancy and the first several months following delivery showed no variations which could be attributed to the pregnant condition. The duration of the growth

period was longer for the longer hairs (pubic and perineal) than for the shorter hairs (lumbar). The quiescent period of the follicular cycle was longer than the growth period in the lumbar region, considerably shorter than the growth period in the perineal region, and only inappreciably shorter in the pubic region.

CLINICAL SURGERY

FROM THE STANFORD SURGICAL SERVICE

AN OPERATION FOR TUBERCULOUS EMPYEMA

L. ELOESSER, M.D. F.A.C.S. SAN FRANCISCO, CALIFORNIA

From the Stanford Surgical Service of the San Francisco Hospital, Department of Public Health

THE ordinary form of rib resection with introduction of a drainage tube is notoriously unsatisfactory in tuberculous empyema, especially in empyemas the pus of which contains either tubercle bacilli alone or no demonstrable organism at all i.e. empyemas not secondarily infected. So called closed drainage, drainage by means of a tube introduced into an intercostal space through a trocar is equally bad. Both of these methods always lead to secondary infection and almost always to fever, sepsis, and death.

Some forms of tuberculous empyema, however, occasionally purely tuberculous ones, more often secondarily infected ones, produce such constantly high swinging temperatures and such severe symptoms of toxicity that surgeons are impelled again and again to drain in spite of previous warnings and in spite of full knowledge of the trouble that usually ensues.

Several methods of treatment are proposed for such toxic tuberculous empyemas. Aspiration with a syringe, replacement of the pus by an equal quantity of air and irrigation of the pyopneumothorax cavity with countless varieties of antiseptic solutions have been recommended. Aspiration often results in abatement of fever and sepsis for a few days and even weeks, but usually needs to be repeated so often and so long that both the doctor's and the sufferer's patience are exhausted. At times it leads to cure, usually not.

Oleothorax (injection of gonemol and various other antiseptic or aseptic oils) has led to good results in some hands (Matson) to disastrous results in others.

Extensive thoracoplasty may succeed in obliterating the empyema cavity but the operation needs be extensive and formidable. It entails considerable risk to patients weakened by long toxic illness and considerable crippling at best.

Cure of these tuberculous empyemas is made difficult by the tenacity with which the underly-

ing lung resists expansion. It is also made difficult by the unfavorable effect of an indwelling drainage tube of any kind. The presence of the tube itself, I think, tends to keep up fever and sepsis. Some tuberculous empyemas treated ill advisedly by rib resection and drainage heal if one does nothing more than remove the drainage tube.

A desire to obviate a drainage tube led to an operation which has proved of use in a number of secondarily infected tuberculous empyemas. Encouraged by its success it has with some hesitancy recently been used in a few obstinately toxic tuberculous empyemas, in which no pus forming organisms could be found.

The operation causes the underlying lung to expand. It is, therefore, *not applicable* to those empyemas in which the lung is so badly affected that expansion to any degree seems inadvisable. The question of applicability must be decided by clinical pulmonary symptoms and especially by X-rays taken prior to the appearance of the complicating empyema. If cough and expectoration of baciliferous bearing sputum still persist and if early roentgenograms reveal large cavities or other extensive parenchymal damage, some form of thoracoplasty is probably safer. Fortunately, in many empyemas the lung seems little if at all affected and partial if not total expansion seems allowable. If but partial expansion seems advisable the operation to be described should be complemented by an upper thoracoplasty.

TECHNIQUE

Under local anesthesia a U-shaped flap of skin and subcutis is outlined about half way between the posterior axillary line and the line of the inferior scapular angle. The flap has a base about 3 inches wide which lies about one rib higher than the bottom of the empyema cavity so that the rising diaphragm may not stop drainage. It is about $3\frac{1}{2}$ inches long, the length of two ribs and

Fig. 1 Flap of skin outlined

their intercostal spaces long enough to reach into the pleural cavity with out the least tension and longer therefore in fat patients than in lean ones. The rib underling the top of the flap is resected the amount resected equalling the width of the flap. If the flap is too narrow and the resection too scant drainage will be insufficient. It is good

I think, to strip the rib with a cautery instead of a raspatory and to inject the bared intercostal nerve with 1 cubic centimeter of absolute alcohol. The tip of this flap is turned into the chest and tacked to the pleura with one or two chromic catgut stitches the edges of the defect in the skin are approximated with a few stitches of silk worm.

This thoracotomy needs no tube for the skin flap which lies against the soft parts of the chest keeps the wound open. It remains open until the lung reaches the chest wall after which it spontaneously and automatically closes without further ado. It has a valve action each cough or rise in intrapulmonary air pressure expels a little air

Fig. 2 Cross section of chest wall showing skin flap turned into chest and attached to pleura

Fig. 3

Fig. 3 Skin flap turned into chest cavity edges of defect approximated by sutures

from the thorax and causes a gradually increasing negative pressure in the empyema cavity, for it is more difficult for air to enter through this valve-like wound than to escape from it. This fact is readily demonstrable (although in theory the valve might seem to work the other way) if

the wound is opened by an instrument at a change of dressings when air will enter it with a sucking sound. If much negative pressure is desired over zealous and overcleanly nurses should be cautioned not to change the dressings or to content themselves with changing the outer ones only and to leave the inner ones in place as long as possible—for many days.

This operation it will be seen differs entirely both in theory and practice from the valve recently proposed by Nichol for acute empyema. Details with X rays case histories and other data will soon be published.¹

BIRTH FRACTURES OF THE FEMUR

ÅKE RYDÉN M.D. LUND, SWEDEN

From the Obstetrical and Gynecological Clinic, University of Lund, Sweden, Professor Elis Ekström-Möller, Chief

THE problem of caring for fractures of the newborn the result of birth injuries occupies a rather unique position in medical science in that it concerns no particular specialty. This fact at once becomes evident when search is made in the literature reference must be made not only to the obstetric and pediatric, but also to the orthopedic and surgical literature. It is surprising moreover how little has been written on the subject at least in so far as data regarding the final results are concerned.

For the purpose of acquiring a wider knowledge of the entire problem study has been made of the fracture material found at the Obstetrical Clinic in Lund during the years 1900-1934. It is the preliminary report of this investigation that I present in this paper. The present report concerns fractures of the femur only.

During the study three main points were kept especially in mind: (1) the immediate process of healing, (2) the prognosis, especially with respect to the end result, (3) the best treatment.

Only brief mention will be made of our findings regarding these points as brought out in our study of the literature.

As to the immediate process of healing it is well known that the healing tendency in infants is great and that even a severe displacement can be remolded into an anatomically good result through the forces of nature (v. Reuss, Naujoks).

As to the final results, the accounts given in the literature are very few. As a rule however it is evident that the favorable result of primary union has been taken as a warranty that the final result will also be good. A few isolated reports of poor results, especially regarding resultant shortenings, have been made (Staffier, Krukenberg, Naujoks). In these cases, however, the time of final examination was not more than 10 years after birth.

The question of treatment has received more attention in the literature than the two other points in question, and a number of different methods have been recommended. Up to the present time, however, no definite agreement has been arrived at as to which is the best method. Generally speaking the methods proposed may be classified into two main types: fixation without extension on the body (Crédé, Kuestner, Dollinger and others) by means of plaster of Paris (Dollinger) with splints (Labatier, Spitzky) and

extension in some form (Schede, Riise, Jones, Oert, Schanz, Gordon and others). Of these two different types of treatment, the former that is, simple fixation without extension, may be said to be employed in more cases than is the extension method.

AUTHOR'S STUDY OF CASES

My own study of the records of the fractures occurring at the Obstetrical Clinic in Lund show that in approximately 40,000 deliveries there were 16 fractures of the femur. All of these fractures, except 2 occurred in breech presentations. Of the two exceptions one occurred in delivery by cesarean section the other in the manual bringing down of an extended leg. The oldest fracture dates from 1914.

With reference to the first point as to the immediate process of healing, an examination of the 13 remaining fractures (3 infants died during birth) confirms the statements made in the literature as regards rapid healing. Union of the fractured bones is so rapid that, on the basis of weeks as a suitable unit of time in the treatment of fractures in adults, we must reckon with days in infants—soft callus appears even in a few days, and bony callus has been observed even in the first week (Bors). This emphasizes the fact that definite reposition should be completed within this time otherwise the opportunity of obtaining a satisfactory position will be lost at least lateral dislocations and shortenings will then be difficult to correct. Indeed the majority of reports of our cases, as they now appear in the records and in the roentgenogram, bear witness to the difficulties encountered for it is evident that in spite of repeated attempts at reposition and fixation the fractures were usually left to unite in an anatomically bad position.

The most common malposition is, as appears from the illustrations, medial displacement and flexion of the proximal fragment, this malposition being produced by the contraction of the flexors and adductors inserted on this fragment. Shortening is also a usual finding and is generally marked in certain cases it may be at least one fourth of the length of the femur (Fig. 6).

Oseous union occurred, however in all cases and sufficient firmness was acquired within 14 days. In those cases in which the process of healing was followed by means of radiographic exam-

Fig. 1 left Fresh fracture of the femur. The three following illustrations show the rapid healing and spontaneous correction.

Fig. 2 The same fracture after 3 weeks. Large callus. No better position could be obtained. Extension was not tried.

inations for somewhat longer periods after fracture it was evident how wonderfully even severe malpositions were modified and gradually assumed a position quite satisfactory anatomically. It should be noted that this process of remodeling has taken place for the most part during the first 6 months of life and not, as might be expected after the child had commenced to stand on its legs (Figs. 1-4). Hence there is no need of weights to guide the spontaneous correction of the malposed member; the normal tonus and play of the musculature seem to be sufficient for this purpose.

Thus, in spite of the fact that in general the fractures were allowed to unite in an anatomically unsatisfactory position, osseous union always did occur; second, the malposition was spontaneously reduced in a rather short time. As we shall bring out later, no inconvenience has been experienced and no suffering has been noted in the early period of growth. The result as to primary healing can therefore quite justly be characterized as good.

In order to obtain an idea as to the final result in these cases, follow-up examinations of the 6 oldest fractures of the femur were made. A brief summary of these 6 cases follows:

CASE 1. No. 495/1924. Male child had a fracture of the left femur following breech presentation. Labor was long and extraction was accomplished by fillet. The fracture was fixed in various ways for a period of 3 weeks. The result was healing in bad position. Healing was normal and patient learned to walk when 16 months old. He has never had any subjective trouble. In 1933, Dr. Brandberg reported that the boy was then 9 years of age and the roent-

Fig. 3 left The same fracture after 7 weeks. Spontaneous correction has commenced.

Fig. 4 The same fracture after 10 months. The position is good.

genogram showed a marked, even, forward curvature of the upper part of the femur. The left leg was 0.5 centimeter shorter than the right. A certain forward curvature was also visible in the upper part of the thigh (Figs. 5-7).

CASE 2. No. 907/1919. A female infant received a fracture of the left femur during prolonged labor, breech presentation, and extraction by fillet. Fixation along the trunk was maintained for 14 days. Primary position of fragments was bad. The process of healing was normal. Patient learned to walk in the usual time and had no subjective trouble until the last 2 years when she began to notice that the left leg was weaker than the right but the weakness was so slight that it was hardly noticeable. In 1934, when she was 15 years old, an X-ray examination showed only a slight trace of the fracture. Both legs were of equal length. The left thigh was 1.5 centimeters smaller around than the right thigh; the left calf was 0.5 centimeter smaller. A near result of the application of the fillet, was noticeable in the medial part of the groin (Figs. 8-10).

CASE 3. No. 418/1919. A male infant in breech presentation received a fracture of the left femur during delivery. The mother was febrile and extraction was accomplished by fillet. Fixation of the fracture was maintained for 18 days. No roentgenogram was taken. Normal union took place and patient learned to walk at the usual time. He has never had any subjective symptoms. In 1934, when he was 15 years old, examination showed no more than a trace of the fracture. The legs were of equal length. In circumference the left leg measured 0.5 centimeter less than the

right. A plainly visible scar was noted in the groin the result of the application of the fillet. The ability to extend the leg was somewhat limited in both hip joints. Marked lumbar lordosis with pelvis projecting backward was noted (Figs 1-12).

CASE 4 No. 504/014. A male infant received a fracture of the left femur during delivery. The child was in breech presentation and threatening asphyxia prompted extraction by fillet. Fixation on trunk was maintained for 3 weeks. Primary position was bad. Healing proceeded normally. Patient learned to walk in the usual time and had no trouble during childhood. He began to notice symp-

oms at the age of 5 or 10 years but even though pain increased slightly it was only moderate at all times. He walked with a raised heel. In 1934, at 20 years of age, the roentgenogram showed but a very slight trace of the old fracture. The left leg was almost 2 centimeters shorter than the right, at the thigh it was 2 centimeters more around. The pelvis was oblique (Figs 13-15).

CASE 5 No. 058/014. A female child, in breech presentation suffered a fracture of the left femur during delivery. Labor was atonic. Extraction was accomplished by fillet. Fixation to trunk was maintained for 8 days. Primary position was bad. Union took place normally and patient

learned to walk 2 months later than her twin sister. A new fracture of the same femur was sustained when she was 5 years of age. Apart from the latter fracture, no subjective symptoms were noted either before or after. In 1934, when patient was 20 years old, a roentgenogram showed only a trace of the fracture. The left leg was 2 centimeters shorter. Girth of both thighs was the same. The pelvis was oblique (Figs. 16-17).

CASE 6 No. 34/1914. A male infant had a fracture of the right femur sustained during birth. The child was in transverse position; delivery was accomplished by version and extraction by bringing down the extended leg. Frac-

Fig. 12. The same case as in Figure 11 at the age of 15 years. Scar after the fillet in the left groin. Reduced extension in the hip joints. Lumbar lordosis. Case 3.

ture was held in position by fixation to trunk. Primary position was rather bad. Healing proceeded normally. He learned to walk in the usual time and never had any subjective trouble; in fact he enlisted in the standing army. In 1934, Dr. Thunström reported that patient, then 20 years

Fig. 13.

Fig. 17a

of age, showed hardly any trace of the fracture by roentgenogram, the right leg was 2 centimeters shorter than the left, the girth of both thighs was equal, the pelvis oblique compensatory scoliosis was noticeable (Figs. 8-10).

SURVEY OF CASES

What has just been said with reference to the result of the primary healing is therefore clinically confirmed by these cases. No trouble has been experienced by the patients from birth fractures during the age of growth, all of them learned to walk in the usual time, with the possible exception of Case 1. Thus, even from a clinical point of view the result of the primary healing has been good.

As to the final result, the roentgenographic anatomical examination shows that even in this respect the result has been good. Of the 6 patients who were followed up, and whose ages varied from 9 to 20 years, 5 showed scarcely any trace at all of the old fracture in the roentgenogram. In 1 case there still remained a curvature at the site of the old fracture. Hence the end-results in this respect are very satisfactory. This is true, however, only from a pure roentgenographic anatomical point of view. In other respects some change or other remains discernible.

Two of the patients (Cases 2 and 4) have experienced subjective trouble, very slight, it is true, but noticeable. One of them has a shortening of 2 centimeters. Another patient (Case 6) has a shortening of 3 centimeters. One patient (Case 3) has only a scar in the groin to remind

him of the fracture, a deep lumbar lordosis and somewhat restricted power of extension in the hip joints of this patient cannot with certainty be ascribed to the fracture. In one of the patients (Case 1) the curvature of the femur mentioned is discernible to the naked eye as a forward bending of the thigh. Another of the patients (Case 5) had a new fracture of the same femur when she was 5 years old (for which reason no definite judgment can be formed with regard to the final result, still it is quite possible that the second fracture occurred in a *locus minoris resistentie* at the site of the original birth fracture (no roentgenogram was taken on the second occasion).

Now the question arises as to whether on the whole any significance is to be attached to these changes as shown in a study of the final results. It may be thought that owing to the fact that they are so minute they should be regarded as of no importance. It is interesting to note that in those cases in which trouble has been experienced

Fig. 18

Fig. 19

Fig. 19a

Fig. 19b

Fig. 19. Patient now 20 years old. Fracture is scarcely visible. There is, however, a shortening of 2 centimeters. Case 6.

Fig. 19a. Compensatory scoliosis with convexity to the side of the shortened right leg. Case 6.

Fig. 19b. The same case as in Figures 18 and 19. Shortening of the right leg. The pelvis is inclined with spina iliaca anterior superior and the gluteal fold lower on the right side than on the left. Patient has a scoliosis with the convexity to the right. There is a deep impression present in the right groin which has been left by the fillet. Case 6.

the trouble did not manifest itself until several years after birth. This may signify that such difficulty will increase as the patient grows older and too the possibility cannot be excluded that the patients who are at present free from symptoms will later on in life develop symptoms of

static insufficiency. Thus we should not allow ourselves to be deceived by the beautiful roentgenograms obtained in the following examinations but rather bear in mind that in a clinical sense the result may not always be entirely in accord with the X ray picture.

TREATMENT

From what has been said it is evident that the treatment must aim at a definite result so that even the ultimate result will be entirely satisfactory. This point merits special emphasis since the difficulties encountered in treating fractures in these little patients where the primary union is almost always good may otherwise encourage carelessness.

The treatment employed up to last year at this clinic was fixation of the fractured leg close to the body with the foot at one of the shoulders sometimes with, and sometimes without wooden splints. In exceptional cases plaster of Paris or metal splints bent at right angles have been used (Spitar). The period of fixation has in general been 2 to 3 weeks. The patients have then been discharged and no further treatment has been given. Extension treatment was not employed previously but was introduced last year. The advantages of this latter method of treatment have, however, been so great that it should undoubtedly be preferred to simple fixation. Shortening perhaps the most important malposition, cannot possibly be avoided but by extension (Fig. 24).

The type of extension employed at this clinic was first advanced by Schanz (1928) and later on also described by Obadalek (1933). The principle of this method is to make extension possible without having to fix the child to an uncomfortable cot, which is rather difficult to move about. With this method the child can be easily carried about with the entire extension apparatus applied. Similar methods have been previously mentioned by Boorstein, Gordon, and others.

Fig. 25. The same case as in Figures 23 and 24 after 11 months

Of the older methods the simple fixation treatment, with or without splints, also possessed the same advantage that it allowed the child to be carried round but it had one drawback in that it frequently gave an unsatisfactory reduction of the fracture and required almost daily dressing. The extension treatment in which the extension apparatus was attached to a bed (Schede) had the advantage of giving a better reducing result but it was inconvenient for one thing because it rendered nursing difficult.

The new method of extension introduced by Schanz combines the advantages of the two older methods mentioned without possessing any of their disadvantages. The technical arrangements are simple as may be seen from the pictures (Figs. 20-21). On a bed of plaster of Paris an extension gallows made of iron is fixed on a level with the hip joints. This device may be jointed at the base. A new plaster-of-paris bed can be made for each separate case, the extension gallows being adjusted to the hip of the child, or to one of its shoulder joints in the case of a fractured humerus. If desirable the surgeon may have four such beds in readiness, one for each extremity. The apparatus can easily be made by any blacksmith or ordered from some firm of instrument makers. The application of the extension device to the fractured limb can be performed by means of zinc glue or mastoid but the simplest way is to use a good quality of common adhesive plaster.

The weight extension is generally made so heavy that the lower part of the patient's body is lifted a little from the plaster-of-paris bed. The patient is then suitably held to the bed by means

of a wide bandage. The period of fixation varies from 2 to 3 weeks.

Although the entire arrangement may perhaps appear rather complicated, it is in fact very easy to superintend during the course of treatment. If the apparatus is ready for use the work of attaching the child to it can be accomplished in a very short time. That it fixes the fracture in a firmer manner than by fixing the limb on the body is evidenced by the fact that the child's crying is considerably less when the leg is extended. An other advantage is that, once the extension bed has been applied to the fracture there is no need of repeated bandaging or so much supervision as in the majority of other methods of fixation. A fracture once reduced can be easily kept in position by this method. Finally, it does not in any way hinder nursing (Fig 22). Its main advantage, however, is that it insures a better reduction than any other treatment without extension.

SUMMARY

An investigation has been made of the records of birth fractures at the Obstetrical Clinic at Lund during the years 1900-1934. During this period 16 fractures of the femur occurred. Three children died in connection with delivery. The 13 remaining were examined.

1 Reposition was always difficult. The fractures were frequently left to unite in an anatomically unsatisfactory position. Osseous union has always occurred, however, in a short time. The mal union has been reduced by a spontaneous remoulding into a satisfactory position in the course of the following months. No trouble has been experienced by the patients during the period of growth. The children all learned to walk in the usual time. The *primary healing result* has therefore been good.

2 The examination of the *final results* in the 6 oldest patients at present from 9 to 20 years of age, has shown that in 1 case there still remains a marked curvature of the femur at the site of the old fracture whereas in the 5 other cases hardly any trace of the fracture can at present be seen in the roentgenogram. In several cases however various changes were observable, such as, subjective trouble and shortening. These changes were indeed very slight but they cannot be denied every importance.

3 The best *method of treatment* has been found to be extension, the method employed being ex-

tension in a portable plaster-of paris bed (Schanz 1928). Reduction should be completed after the first few days or at any rate within a week of the occurrence of the fracture. Otherwise it will be rendered more difficult on account of the early formation of callus.

PERIPHERAL NERVE BLOCK IN OBLITERATIVE VASCULAR DISEASE OF THE LOWER EXTREMITY

FURTHER EXPERIENCE WITH ALCOHOL INJECTION OR CRUSHING OF SENSORY NERVES OF LOWER LEG

R. H. SMITHWICK, M.D. F.A.C.S. AND J. C. WHITE, M.D. F.A.C.S. BOSTON, MASSACHUSETTS
The Peripheral Circulatory Clinic, Massachusetts General Hospital

FOUR years ago we reported a technique for alcohol injection of the sensory nerves of the lower extremity (4) in order to relieve the intense rest pain in cases of advanced obliterative vascular disease. At that time our series consisted of 11 cases and the immediate results were gratifying both to us and to the patients. Since then we have employed this procedure in over 50 patients. Sufficient time has elapsed to report our results in the first 45 cases, and to state our present feeling in regard to the value of this operation not only in relieving pain but also as an effective method of treating the disease.

CASES SUITABLE FOR OPERATION

The cases may be divided into two groups according to the pathological process in the vessels (Table I). Twenty-eight were classified under the diagnosis of thrombo-angiitis obliterans, and 17 as arteriosclerosis. We wish to emphasize that the patients in this series are suffering from an advanced stage of the disease with extensive obliteration of main vessels, with severe rest pain, and in nearly every case with ulceration or extensive gangrene. They are not the early cases which usually respond to systematic hygiene, postural exercises, rest, forced fluids, and elimination or curtailment of the use of tobacco, as has been previously described (1). These are cases which for the most part have had a trial of conservative treatment in the hospital for 1 to 2 weeks before resorting to this operation.

ANATOMY AND TECHNIQUE

The anatomy of the lower leg and the technique of operation were described in detail in our first article (4). This will be repeated briefly to emphasize certain points which we believe to be important. Figure 1 shows the position of the five nerves supplying sensation to the foot. It may be necessary to block one or all of these nerves in a given case. They are exposed through small vertical incisions in the middle or upper thirds of the lower leg, under local anesthesia. Only one nerve should be blocked at a time. The others can be done at intervals of a few days to

a week. We believe that too extensive an operation at one sitting may result in rapid advancement of gangrene in the foot, as occurred in one of our first cases. The operation should be done with the greatest care and asepsis. It is essential to know exactly where the nerve in question lies. This knowledge can be acquired only by careful dissection of amputated limbs, and nobody should attempt this operation until he is thoroughly familiar with the course of the nerves. There should be no lateral dissection of the layers. One should be able to place the skin incision exactly over the nerve avoiding intramuscular fascial septa where small collateral arteries are prone to run. Tooth forceps, rake retractors, and such coarse instruments should never be used. In these advanced cases it is almost never necessary to use a hemostat. There are no sporting vessels. If the incisions are properly placed, and the capillary oozing in the fat layer can readily be controlled by gentle pressure with a gauze sponge. When it is necessary to incise the deep fascial layer we do not advise suturing it. Only the finest of plain catgut ties (No. 000) are used when necessary. Silk sutures are placed in the skin without the aid of forceps. Perfect approximation is essential, and sutures should be tied loosely. Operation should never be done in the presence of lymphangitis. Incisions should never be made near areas of migrating phlebitis.

METHOD OF BLOCKING THE NERVE

In the earlier cases (3) the nerve was carefully freed and the surrounding tissues protected by moist gauze. A segment of the nerve, defined between two snug catgut ties, was then distended with 95 per cent alcohol (Fig. 2). The object of this technique was to localize the extent of nerve injected so that the time of regeneration could be controlled and to prevent irregular diffusion of alcohol along the nerve. This we felt was sometimes followed by paresthesias due to incomplete necrosis of nerve fibers at the upper limit of alcohol diffusion. In the more recent cases we have simply crushed the nerve with an instrument over an extent of $\frac{1}{4}$ inch if rapid regeneration was

Fig. 1 Showing the anatomical position of the five nerves supplying sensation to the foot and the areas supplied by each. They can be blocked through small vertical incisions in the middle and upper thirds of the lower leg without causing important motor paralysis. Adapted from John Homans' *Textbook of Surgery* 1935

desired or up to $\frac{1}{2}$ inch if prolonged anesthesia seemed necessary. We favor this latter technique at present because it can be done through a shorter incision, takes less time and avoids the danger of spilling alcohol into the tissues. Crushed nerves regenerate more rapidly and apparently as completely as those injected with alcohol. A nerve crushed over an extent of $\frac{1}{4}$ inch will regenerate in about 3 months. We do not favor actual section and suture of the nerve as has been advocated by Laskey and Silbert, because this would appear to make the operation unnecessarily complicated and difficult, although it would, of course, be equally effective.

COMPLICATIONS

Most of the complications which follow this operation are the result of faulty technique. Among those which we have encountered are delayed healing of the incision, infection in the wound, ulceration of the anesthetic skin as a result of improper weight bearing and unnecessary pressure from poorly fitting shoes, precipitation of gangrene of the foot following too extensive an operation at one sitting.

All of these we have practically eliminated by improvement in technique and careful attention to weight bearing and proper shoes after operation. If the deep peroneal nerve is blocked in the upper third of the leg, paralysis of the extensor hallucis longus may result. In this case an ulcer may develop on the plantar surface of the great toe due to improper weight bearing because of

toe drop. Amputation of this toe may be necessary. The intrinsic muscles of the foot are temporarily paralyzed following block of the posterior tibial nerve. This will be followed by atrophy of the muscles concerned, which as far as we know has never resulted in any important loss of function.

BENEFICIAL SEQUELAE

Besides the elimination of pain, which alone is sufficient indication for the operation, other important changes take place. First of all, the general condition of the patient improves. He is able to sleep, eat, and carry out other conservative measures such as postural exercises. He is able to curtail or eliminate his tobacco. Locally, infection can better be controlled by frequent antiseptic dressings, slough can be trimmed away, and the healing of the wound is greatly accelerated.

The circulation to the part may actually be materially increased because the anesthetic area is completely sympathectomized. Certain of these patients have a large element of vascular spasm as well as obliteration. As the efferent vasoconstrictor sympathetic fibers lie intermingled with the sensory components of the peripheral nerves, they likewise are blocked. The anesthetic area is therefore sympathectomized and the surface temperature may be elevated as much as 15 degrees F in some cases (Fig. 3). This, of course, is temporary and as sensation returns, vascular spasm returns. If the surface temperature rise has been marked, this operation

SURGERY GYNECOLOGY AND OBSTETRICS

TABLE I.—THROMBO-ANGIITIS OBLITERANS

Case No. Hosp. N.	Age	Local lesions	Peripheral vessels Pop. D. P. T.	Nerves blocked	Minor amputation	Major amputation	End result
201495	30	Great toe amputated for gangrene. Severe and severe pain in stump		Posterior tibial	Great toe		Slow but painless healing of de-arterialized toe in months
201496	30	Ulceration of tip of right great toe		Cutaneous branch of peroneal, posterior tibial, right	Right great toe		Terminal phalanx removed, pain relieved, but infection extended along flexor tendon sheath as far as calcus. Toe amputated
		Partial unhealed amputation stump right great toe		Posterior tibial, superficial and deep peroneal, right		Guth-Stokes, right	Pain not relieved because gangrene extended beyond anesthetic area, Guth-Stokes amputation
		Severe pain and discoloration in toes of left foot		Superficial and deep peroneal, posterior tibial, left		Guth-Stokes, left	Pain only partially relieved because gangrene extended into lower leg, Guth-Stokes amputation
201497	30	Continued pain in foot after amputation of second and third right toes for gangrene	+	Cutaneous branch of superficial peroneal, deep peroneal, and posterior tibial	Second and third toes, right		Complete relief of pain. Healed in months
		Partial gangrene left great toe	+	Superficial and deep peroneal, posterior tibial	Left great toe		Toe amputated. Stump failed to heal, pain relieved but suppurated
		Discharging sinus in amputation stump, left great toe	+	Superficial and deep peroneal, posterior tibial, saphenous, and sacral	Second, third, and fourth toes left		Pain not relieved and healing incomplete
		Left foot stump unhealed and infected	+	Superficial peroneal, sacral, and saphenous	Heels of all metatarsals		Complete relief of pain. Healed slowly with skin graft, 3 months after operation
201498	43	Partial ulcer of great toe	+	Posterior tibial, deep peroneal, and cutaneous peroneal		Guth-Stokes	Final amputation, as ulcers did not heal
201499	37	Partial ulcers dorsum of foot and great toe		Posterior tibial, cutaneous peroneal, and sacral			Pain relieved, ulcers healed
201500	45	Partial ulcer of great toe	+	Sacral, posterior tibial, and superficial peroneal		Guth-Stokes	Ulcer failed to heal. Guth-Stokes amputation
201501	45	Partial ulcer right second toe		Superficial and deep peroneal, posterior tibial			Pain relieved. Tip of toe healing on discharge
		Trophic ulcer great toe from too deep and faulty weight bearing			Right great toe		Right great toe amputated
		Partial gangrene right third toe		Superficial and deep peroneal			Pain relieved. Toe healed
		Partial gangrene right second toe		Superficial and deep peroneal, posterior tibial	Right second toe		Pain partially relieved. Toe healed
		Partial ulcer right third toe			Right third, fourth, and fifth toes		Right third toe amputated, fourth and fifth toes normal, compensated for prephyria
		Partial gangrene left great toe, ulcer fourth toe	+	Posterior tibial, superficial and deep peroneal	All toes, heels of metatarsals, second, third and fourth		Great toe amputated, gangrene extended, second, third, and fourth toes amputated, finally fifth toe amputated because useless
		Partial gangrene right third toe	+	Posterior tibial and superficial peroneal	Right second and third toes		Pain immediately relieved. Infection spread, second and third toes amputated
201502	49	Partial beginning gangrene right great toe	+	Superficial and deep peroneal, posterior tibial	Right great toe		Pain relieved but toe still sloughing. Toe amputated, healed well. All symptoms returned after time.

SMITHWICK WHITE PERIPHERAL NERVE BLOCK IN VASCULAR DISEASE 1109

TABLE I.—THROMBO-ANGITIS OBLITERANS—Continued

Case No. Hosp. No.	Age	Local lesion	Peripheral vessels Pop. D P T.	Nerve blocked	Minor amputation	Major amputation	End-result
10 256606	43	<p><i>Early I</i> Painful ulcer with beginning gangrene in stump of right great toe and between fourth and fifth toes</p> <p><i>II</i> Amputation stump of left fifth toe was healed and painful</p>	o	Posterior tibial, superficial and deep peroneal	Right second and fifth toes		Pain relieved. Gangrenous areas became sharply defined; second and fifth toes amputated. Foot amputation advised but patient refused. Discharged with open areas. All nerves regenerated 1 year later. 3 years later still one clean ulcer open
11 205749	33	Painful beginning gangrene great toe and lateral aspect right foot	o o	Superficial peroneal and posterior tibial	Left fourth toe		Left foot amputation advised but patient refused. Gangrene developed at fourth left toe which was then amputated
12 2057	33	Pain in all toes of right foot, great and fifth toes infected	+	Sciatic	Left fifth toe		Ulcer healing and painless on discharge
3 207565	37	Pain in right great toe recurrent (with osteomyelitis)	+	Posterior tibial and superficial peroneal	Right great toe		Toes healing, pain relieved for 3 months
4 203113	44	Left great toe amputated for gangrene, pain in stump	o	Deep peroneal, saphenous, sciatic	Right great toe		Right great toe amputated and sole of foot drained. Healing on discharge
5 211648	33	Painful gangrene right third toe	+	Posterior tibial, superficial and deep peroneal		Left foot at ankle + Grith-Stokes	Gangrene progressed in foot, amputated at ankle 15 days after injection. Grith-Stokes 3 days later
6 207383	36	Infection in left great toe, moderate pain in foot	+	Posterior tibial, superficial and deep peroneal		Right leg below knee	Pain completely relieved but recurred after 1 month. Amputated. Gangrene progressed to ball of foot and pain recurred. Amputation below knee done 6 weeks after injection
7 207547	39	Painful same right fifth toe	+	Posterior tibial			Toes improved but still unhealed on discharge. Nerves all regenerated 6 months later
8 20706	34	Right second, third, and fourth toes amputated, ulcers healed and sloughing, severe pain in foot, especially great toe	+	Sciatic, posterior tibial, saphenous	Right fourth and fifth toes		Pain relieved. Fourth and fifth toes healed slowly and completely
9 21479	39	Amputation stumps of right great and fifth toes painful on dressing	o o o	Posterior tibial, superficial and deep peroneal		Grith-Stokes, right	Gangrene developed in great toe, incision for nerve block did not heal, pain continued. Grith-Stokes amputation done 3 weeks after injection
10 210146	34	Painful ulcer right great toe, dry skin second toe	+	Sciatic, superficial peroneal, posterior tibial	Right first and fifth metatarsals		Stumps of both toes broke down 3 months after section, but only slightly painful. Head of first metatarsal removed, fifth metatarsal stump carried. Four months later amputation of non-healing great toe stump. Took 3 months more to heal. Nerves regenerated 8 months after block
11 2102	35	Painful gangrene in stump of first metatarsal right	+	Superficial and deep peroneal, posterior tibial	Right great and second toes		Pain relieved but toes did not heal. Second toe amputated 9 days after alcohol injection. Great toe developed gangrene 3 months later amputated
12 2102	35	Painful ulcer left great toe, whole foot discolored	+	Superficial and deep peroneal, posterior tibial, sciatic		1 Foot at ankle + Grith-Stokes	Entire dorsum of foot became ulcerated and gangrenous, amputation at ankle then Grith-Stokes

*The average duration of symptoms was 3 years, 6 months in the thrombo-angitis obliterans group, and 1 year 6 months in the arteriosclerosis group. The interval between serious involvement of the two legs in the cases in which bilateral nerve block was necessary was 3 years.

TABLE I —THROMBO-ANGIITIS OBLITERANS—Continued

Case No.	Age	Local lesion	Peripheral vessels Pop D P T	Nerves blocked	Minor amputation	Major amputation	End-result
34 30660	46	Painful ulcer right fifth toe		Sural			Patient returned to hospital 3 weeks after nerve block with ulcer healed though pain improved. Nerve block became useless. After 3 months toe ulcer healed, incision still open. Grafts applied, postoperative sym- ptomatically with success and signi- ficance of sensory loss alone without effect on healing of nerve block in- cision. Lumbar sympathectomy gang- lionectomy done, followed by healing.
35 318377	48	Painful threatened gas- trocnemius claudication of left leg, ulcer at base of great toe	+	Posterior tibial, superficial peroneal, sural	Great and fifth toes left	Orchi- ectomy, left	Gangrene progressed, great and fifth toes amputated, gangrene appeared on fourth toe. Orchi-ectomy ampu- tation of leg done. Pain completely relieved.
36 346132	39	Painful gangrene right great toe, beginning gas- trocnemius second toe	+	Posterior tibial, superficial and deep peroneal	Right great toe		Dry gangrene at tip of great toe re- solved. Amputation, gangrene and ulcers healed 5 months after nerve block.
37 346132	39	Ulcers of great and second toes, left		Superficial peroneal, posterior tibial	Left second toe		Ulcers did not heal. Gangrene devel- oped on second toe. Toe amputated, followed by painful healing.
38 346132	46	Right great toe nail bed infected, whole foot discolored and painful		Superficial and deep peroneal	Right great toe	Right lower leg	Gangrene developed in great toe. Toe amputated. Ulcers failed to heal. Re-amputation foot mechanical in- fection spread. Gangrene ampu- tation of lower leg done, followed by re-amputation 3 inches below knee.
39 346132	46	Left great toe nail bed sloughing	+		Left great toe		Circulation not improved by medical measures. Toe amputated. Amputa- tion wound ulcerated. Lumbar ganglionectomy done, stump healed, wound healed 4 months after ampu- tation.
40 346132	46	Right third and fourth toes ulcer- ated	+				Right lumbar ganglionectomy done. Healing not effected.
41 346132	46	Right third and fourth toes ulcer- ated	+	Posterior tibial, superficial and deep peroneal	Right third and fourth toes		Right fourth toe amputated. Nerve block done for pain in stump. Toe third toe amputated. Slow healing, complete in 6 months.
42 346132	46	Ulceration between left fourth and fifth toes		All 5 nerves	Left fourth and fifth toes and metatarsals		Pain relieved but healing not effected. Toes amputated. Slow healing com- pleted by amputation. Nerve blocks required on return of pain.
43 346132	46	Ulceration left third toe	+		Left third toe		All remaining toes of both feet to be amputated.
44 346132	3	Painful ulcers tips of fourth and fifth toes		Sural, posterior tibial, superficial peroneal		Orchi- ectomy, left	Pain relieved temporarily but 6 weeks later gangrene commenced in fifth toe with severe pain. Superficial peroneal nerve blocked again. Gas- trocnemius extended into foot, poor heal- ing of nerve block incision. Orchi- ectomy amputation done.
45 346132	34	Pain and swelling left leg, ulcers on leg at sites of previous nerve injections		Superficial and deep peroneal, sural, saphenous		Low thigh, gastrocnemius, left	Gangrene developed, low thigh ampu- tation done. Amputation stump pained 1 year later. Posterior lumbar cutaneous nerve blocked. Pain not completely relieved. Stump re-amputated, postoperative healed. Later cordectomy for pain.

*The average duration of symptoms was 3 years, 6 months in the thrombo-angiitis obliterans group, and 1 year, 8 months in the arteriosclerosis group. The interval between serious involvement of the two legs in the same in which bilateral nerve block was necessary was 1 year.

TABLE I—Continued—ARTERIOSCLEROSIS

Case No. Hosp No	Age	Local lesion	Peripheral vessels Pop D P T	Nerves blocked	Minor amputation	Major amputation	End-result
30 184184	43	Beginning gangrene of first 3 toes, left	o	Cutaneous branch of peroneal, and posterior tibial		Gritti-Stokes, left	Gangrene and pain spread rapidly to lower leg Gritti-Stokes amputation
30 196130	70	Threatened gangrene of right foot, severe pain in first 3 toes	o o o	Cutaneous branch of peroneal, deep peroneal, and posterior tibial		Gritti-Stokes, right	Paralese gangrene of foot in 10 days Gritti-Stokes amputation
3 243508	70	Non-healing ulcer lateral lower third of leg	+ o	Peroneal anastomotic and external saphenous branches of sural nerve	Left fifth toe		Ulcer healed slowly and painlessly. Lesion also healed slowly with minor sepsis
3 208163	67	Ulcer of fifth toe with septic point Continued pain after amputation of toe	+ o	Posterior tibial, cutaneous peroneal, and musculo-cutaneous		Lower thigh, left	Relief of pain Gangrene advanced slowly forcing amputation of leg
33- 297497	67	Painful gangrene of left great toe	o o	Posterior tibial		Gritti-Stokes, right	Rapid spread of gangrene Amputation of leg done
34 208100	63	Painful gangrene of right fifth toe	o o o	Posterior tibial, cutaneous peroneal		Right lower thigh	Ulcer continued dirty and sloughing Leg amputated at mid-thigh 3 days after infection
35 10395	55	Large painful ulcer over right tibia, pain extending into foot and up to groin	o o o	Saphenous			Ulcer healed but pain not relieved
36 209043	50	Painful ulcer side of right foot	o o	Sural			Pain completely relieved for 3 mos
37 209043	50	Ulcer side of right foot healed but still painful	o	Sural			Ulcer practically healed, no pain, no regeneration after 3 months
37 209043	50	Painful ulcer re-entrant		Superficial peroneal			Ulcer unimproved, but toe amputated through part of proximal phalanx 3 months later clean ulcer over Fourth toe gangrenous, this amputated. Nerve still completely blocked
37 209043	50	Painful ulcer of left fifth toe		Sural, superficial peroneal posterior tibial	Left fifth and fourth toes		Amputation wound of fifth toe did not heal Leg amputation done 3 months later
38 215584	60	Painful gangrenous stump of right fifth toe	o	Sural, posterior tibial, superficial peroneal	Right fifth metatarsal	Right leg	Slow healing Pain relieved
39 31473	70	Painful ulcer with beginning gangrene in left fifth toe	+	Sural, posterior tibial, superficial peroneal			Wound healing, pain gone except for itching on dorsum of foot on discharge
40 3102	70	Gangrene of left great toe with severe pain	o o o	Posterior tibial, superficial and deep peroneal		Gritti-Stokes, left	Ulcer failed to heal, lymphangitis developed, Gritti-Stokes amputation
41 319083	61	Painful ulcer on dorsum of left foot	+	Superficial peroneal			Stumps healed on discharge Amputation of leg advised, refused by patient Pain entirely relieved
41 319083	41	Amputation stumps fourth and fifth toes unable to tolerate dressings	o	Posterior tibial, sural, superficial peroneal		Left lower leg	Patient returned to hospital 4 weeks after last nerve block with ulcer unhealed and painful, lymphangitis, and threatened gangrene. Amputation at lower third of tibia
42 314630	7	Painful ulcer sole of left foot with discoloration of whole foot	o o o	Posterior tibial, sural, superficial and deep peroneal		Low thigh right	Gangrene spread left foot Low thigh amputation done
44 3138	8	Continued pain in stump of right second toe after amputation for gangrene	o	Superficial and deep peroneal, posterior tibial		Gritti-Stokes, right	Gangrene spread and became more painful Gritti-Stokes amputation done 4 months after block
45 209100	69	Painful beginning gangrene of right foot, especially third and fourth toes	+	Superficial peroneal			

Fig. 2. Method of injecting alcohol into a nerve. Alcohol is injected into a small segment of nerve defined by two long ties. These are later removed. We feel this prevents irregular diffusion of the solution along the nerve which may result in paresthesia rather than anesthesia. The duration of anesthesia depends upon the length of the segment of nerve which is injected.

should be followed by lumbar ganglionectomy in selected cases. Lastly the anesthetic area is dry. This diminishes heat loss from the skin surface by radiation and convection, which are much greater in the presence of moisture.

RESULTS

It is of course difficult to compare the results of this series with those obtained in a similar series not treated by this method. Table II gives a comparison between the first 25 consecutive cases of thrombo-angitis obliterans treated by this method and the preceding 25 similar cases treated by other methods. It shows a marked increase in the number of successful minor amputations and a marked decrease in the number of major amputations necessary in the cases treated by

TABLE II.—THROMBO-ANGITIS OBLITERANS

	25 cases without nerve block	25 cases with nerve block
Amputation unnecessary	1	4
Minor amputations	7	14
Unilateral major amputations	11	0
Bilateral major amputations	6	1
Percentage of involved extremities having major amputations	74%	30%

Showing a decrease in the number of cases in which no amputation is necessary, an increase in the number of successful minor amputations, a decrease in unilateral major amputations, and a striking decrease in the number of bilateral major amputations in the nerve block cases.

nerve block. We would particularly call attention to the decrease in the number of necessary bilateral major amputations in the nerve block series. Table III shows the distributions of major and minor amputations in this series of 45 cases. Again we would emphasize the fact that only one bilateral major amputation was necessary in this series. Five cases required amputation of one or more toes in both feet, but were saved from bilateral major amputations. In our opinion these good results were due solely to this operation. Figures 4 and 5 show end-results in 2 cases.

The results are better in the patients with thrombo-angitis obliterans than in the arteriosclerotic group as shown in Table IV, where the influence of the different pathological processes is brought out. As has been previously emphasized, the average age is much less and the duration of symptoms much longer in the patients suffering with thrombo-angitis obliterans (1). This, of course, gives a much better opportunity for the development of collateral circulation. The presence or absence of popliteal pulsation is important in both groups from the point of view of end-results, but less so in the case of thrombo-angitis obliterans. Here one is much more likely to avoid a major amputation in the absence of popliteal pulsation than in the arteriosclerotic group (Table V).

To speak for a minute about minor amputations. We are impressed by the fact that the difficulty usually involves one or two toes, rarely more. After these have been successfully healed with the aid of minor amputations, there are left two or three useless toes which in our experience are very apt to get the patient into future serious difficulty because of minor trauma and poor hygiene. In several cases we have had to block the same nerves several times on different entries for successive gangrene of one toe after another. The nerves had regenerated between admissions. We are favorably impressed by the results of prophylactic amputation of these remaining superfluous toes by the method of lateral slips through the middle of the proximal phalanx, as

TABLE III.—AMPUTATIONS

		45

Fig. 3. Surface temperature rise after nerve block. Case 24 (Table I). Chart showing a surface temperature rise of nearly 20 degrees F. in the right great toe following nerve block. After spinal anesthesia, which paralyzes the lumbar sympathetic trunks, there is no further rise of surface temperature in this toe, suggesting that it has been very completely sympathetomized by peripheral nerve block. The surface temperature of the left great toe, however, does rise approximately 18 degrees F. for the duration of the spinal anesthesia. (Reproduced by permission, *New England Journal of Medicine* 3.)

shown in Figure 5. This almost ensures the patient against future episodes of ulceration and gangrene which usually start in the tip of a toe and rarely in the foot itself. The resulting foot with the heads of the metatarsals preserved is functionally satisfactory provided the toe of the shoe is stuffed with sponge rubber or lamb's wool to prevent sliding forward into the shoe. At times a $\frac{1}{4}$ inch metatarsal bar is a great help.

Practically all of the major amputations in this series were of the low thigh or Gritti Stokes type. We are not favorably impressed by the end results in lower leg (point of election) amputations for advanced obliterative vascular disease. Recurrent ulceration and pain are so frequent that they become of great economic importance

TABLE IV

Disease	Extremities involved	Major amputations number	per cent
Thrombo-angitis obliterans	34	12	35.3
Arteriosclerosis	17	10	58.8

Showing the influence of the pathological process upon the loss of extremities. Major amputations are relatively more frequent in the arteriosclerotic group.

and in many cases prevent the patient from using his permanent leg much more than 50 per cent of the time. The only cases in which we occasionally do point of election amputations are young individuals who are thin and in whom the probability of loss of the other extremity is great. We have several patients (only one in this series) who have had bilateral Gritti Stokes amputations and get about very well on a pair of short legs. From the preceding remarks it is obvious that major amputations are still necessary at times although we

TABLE V

Disease	Number of extremities	Major amputations Number	Per cent
Popliteal pulsation present—			
Thrombo-angitis obliterans	16	4	25.0
Arteriosclerosis	7	3	42.9
Popliteal pulsation absent—			
Thrombo-angitis obliterans	17	8	47.1
Arteriosclerosis	11	8	72.7

Showing the influence of extent of obliteration upon the end-result. Major amputations are more frequent in the absence of popliteal pulsation, particularly in the arteriosclerotic group.

Fig. 4 End result, Case 3 (Table I). Loss of second and third toes of right foot and all toes and heads of all metatarsal bones of left foot.

Fig. 5 End result, Case 36 (Table I). After multiple amputations, minor amputations, and repeated nerve block, the first, third, and fifth toes of the right foot and the third toe of the left foot were amputated before they became involved.

feel that this operation has enabled us to more than double the number of successful minor amputations and to more than halve the number of major amputations. We believe it has also increased the number of cases in which no amputation is necessary. We still intend to do major amputations only in the presence of hopeless gangrene or sepsis which endangers the life of the patient.

CONCLUSIONS

1. Peripheral nerve block is an effective method of controlling rest pain in patients with advanced obliterative vascular disease.

2. Besides controlling pain, the circulation to the part may be increased because the anesthetic area is also deprived of its vasoconstrictor nerves.

3. Local infection in open lesions is more easily controlled because frequent antiseptic dressings can be done painlessly.

4. The general condition of the patient improves with the relief of pain and other conservative measures become more effective.

5. The operation requires careful technique, asepsis, and should be done in multiple stages. Under these circumstances complications are few.

6. The nerves may either be injected with alcohol or crushed. The latter method is more simple and equally effective, although the nerves regenerate more rapidly.

7. We believe that this procedure has more than halved the number of necessary major amputations, and more than doubled the number of successful minor amputations. It also has

increased the number of cases in which no amputation is necessary. We would particularly emphasize the striking reduction in bilateral major amputations in this series.

8. The results are better in the patients with thrombo-angitis obliterans than in the arteriosclerotic group. Patients with pulsation of the popliteal vessels do better than those in which the vessel is obliterated at this level.

9. Amputation of uninvolved toes is an effective prophylactic procedure in selected cases. If the vasomotor index is high, lumbar ganglionectomy should be done after the peripheral nerves have regenerated in certain cases.

10. Unless hopeless gangrene or infection sufficient to endanger the life of the patient is present, this operation should be tried before resorting to a major amputation. It is not indicated in the early treatment of obliterative vascular disease, but should be used in advanced stages after other conservative methods have proved inadequate.

URETERO-INTESTINAL IMPLANTATION WITH DRAINAGE BY EXTRAPERITONEAL CATHETER

FRANK HINMAN M.D. F.A.C.S. SAN FRANCISCO CALIFORNIA

IN 1925 Smitten reviewed 755 cases of uretero-intestinal implantation reported in the literature with an average surgical mortality of 33.6 per cent. Twenty nine per cent of the patients died of peritonitis and 23.4 per cent of severe pyelonephritis. Shock and pneumonia were common complications. The course of patients surviving the operation was not given. Doubtless many of them died of ascending infection or from slow renal obstruction.

This is a good representation of the experience of others. To put the ureters in the bowel always involves the two risks of infection and obstruction. The facts that birds and some reptiles normally have ureters ending in a cloaca full of pathogenic organisms and that many surgeons have been successful in imitating this anatomical relationship to the extent that patients live many years with neither of the two complications account for the belief of many surgeons that a method which will minimize these great risks will be found. Surgical efforts thus inspired go in waves and there is one of limited enthusiasm sweeping the country at present.

Almost every conceivable idea to prevent infection and ureteral obstruction has been tried. One of the important causes of failure with many methods has been the obstruction to a free outflow of urine caused by the congestion and edema at the site of implantation. Temporary obstruction from this cause may be the starting point for an acute obstructive pyelonephritis with multiple abscesses. If only one ureter has been transplanted this renal infection may subside and the kidney recover when urine begins to drain freely following the disappearance of the local edema. If bilateral transplantation has been done, the condition is much more serious. Statistics clearly show that in case of exstrophy it is safer to transplant one ureter at a time. In old people with cancer of the bladder however, every extra stage of surgery multiplies the risk by that much and a technique is needed which does not increase the risk if both ureters are transplanted at the same operation. Higgins's modification of Coffey's technique III¹ and Poth's modification of Higgins's technique² are good for two reasons, and have been performed successfully. In the first place the bowel is not opened and the technique is aseptic. In the second place, urine drains natu-

rally into the bladder and the intestinal wound about the ureter heals without contamination either of urine or faeces and without producing urinary obstruction caused by the edema of surgical trauma. However drawing the ureter over to the rectum for anastomosis without dividing it may be difficult sometimes and if the ureter is on tension when the operation is done, the ureter may be found detached at the second operation and the whole purpose be defeated.

First stage. The ureters are exposed but not divided. A portion of each is imbedded in a suitable channel of the muscular layer incised to the submucosa. The hidden intestino-ureteral suture (Koser's to Hansen) is placed. Urine drains naturally until the hidden suture cuts through.

Second stage. Each ureter is divided just below the portion which has been imbedded.

First stage. The ureters are unbedded as above but the hidden suture is not used. The lumen of the ureter is not connected with the lumen of the bowel at this time. **Second stage.** An opening of the ureter into the bowel is made with a cautery passed up the ureter after its division below the portion imbedded and this cautery is drawn out by an assistant through a proctoscope in the rectum.

Fig. 1. The right ureter is dilated and straight and the pyelogram shows a cavity formation, indicating tuberculous involvement. The urine from the right kidney shows tubercle bacilli. There is questionable involvement of the upper pole on the left. The urine from the left kidney is negative.

Fig. 1. A, The incision. B, Extrapertoneal exposure of the ureter which is ligated and divided near the bladder after the peritoneum has been opened and the abdomen inspected, as shown in Figure 3, and not at this stage.

A well known method of diversion of urine during the period of healing is nephrostomy. Preliminary drainage by nephrostomy reduces the risk of implantation but adds another operation. Of 7 patients on whom this was done 6 survived. The 1 who died (2 days after bilateral implantation, by Coffey's catheter technique of shock and acute dilatation of the stomach) had an extensive carcinoma of the bladder and urethra. Unilateral implantation was done in each of the 6 patients who recovered. Each had one kidney and a contracted tuberculous bladder; nephrectomy for tuberculosis having been done sometime pre-

viously in all. Two are still living comfortably; 1 lived for 3 months and the others for over a year. Four of the 6 patients died of non-surgical causes long after operation and, except in 1 patient, the cause of death was unrelated to the implantation. One died in 3 months of military tuberculosis (autopsy); 1 in 13 months of right-sided lobar pneumonia (autopsy); 1 in 3 years of unknown cause (no autopsy) probably renal insufficiency and 1 in 4½ years of calculous anuria (stone in the implanted ureter) (autopsy). Nephrostomy was indicated in these cases of tuberculosis as a therapeutic measure in itself.

Fig 3. The peritoneum has been incised alongside that portion of the pelvic colon favorable for ureteral anastomosis and the ureter after division near the bladder is drawn out through this incision.

regardless of its relationship to ureteral implantation. Finding that the remaining kidney is free of tuberculosis, demonstration of a fairly normal ureter and of restoration of function when it had been reduced before nephrostomy give the indications for implantation of the ureter. Patients with contracted, hopelessly involved bladders get along quite comfortably with simple nephrostomy. Three such patients are now living 5, 2 and 1 years respectively with symptomless bladders and nephrostomy drainage, one because he prefers the nephrostomy tube to another operation and the other two because the lower ureters are so badly diseased that the operation

never has been proposed. However nephrostomy should not be the routine procedure in this type of case. The soundness of the remaining kidney and ureter can be determined by tests of total function and excretory urography even when the ureter cannot be catheterized and the ureter can be implanted at once without preliminary nephrostomy. Recently 2 patients, each with a nephrectomy for tuberculosis, and a tuberculous bladder but with good renal function and a normal appearing ureter have weathered direct implantation of this solitary ureter by a simple seven suture method without drainage (to be reported). The other tuberculous patients in poor

Fig. 4 The ureter is incised as high as possible under the peritoneal flap and a retention catheter is inserted. The end of this is brought out retroperitoneally.

condition succumbed from nephrostomy alone. Drainage by preliminary nephrostomy should not be regarded as a stage of uretero-intestinal implantation. It only complicates the problem by adding more surgery. It has, however, its own indications. In some patients wearing a nephrostomy tube uretero-intestinal implantation may become indicated and the fact that good drainage already is established lowers the risk of operation.

Coffey's enthusiasm over the results of catheter drainage (technique II) as a preventive of obstruction, thus permitting bilateral implantation at one operation, has led to its trial by a great many surgeons. In memory of the debt owed this

surgeon for his faithful prolonged study of the problem, it should be said that he himself regarded this method as imperfect and at the time of his death was working for a better one. The catheter which is tied to the ureter and therefore cannot be withdrawn until the ureter sloughs off is in itself a cause of complications, some of which may be fatal. Trouble originating directly from the catheter occurred in 6 of my 15 patients operated upon by this technique and 2 died in consequence of such complication. Table I.

Extraperitoneal drainage after ureterotomy for stone at any portion of the ureter is a common experience of urologists. When Coffey first dis-

Fig. 5 The ureter has been implanted by technique III of Coffey and the site of implantation is covered by the flap of peritoneum, leaving the retention catheter to drain extraperitoneally

Fig. 6 Illustrates how the area of implantation can be drained retroperitoneally

cussed the aseptic advantages of the hidden suture (technique III) it occurred to me that extraperitoneal drainage as after ureterolithotomy might be used to advantage in conjunction with this technique. The trial of this method has been made in 3 patients with a good result in 2 but a fatal complication from the catheter in the third. The cases are reported in order to place on record this modification of method and at the same time to condemn it. A retention catheter in the ureter draining extraperitoneally carries the same element of danger as Coffey's Technique II with catheters draining transrectally. The accompanying illustrations explain the method as well as would description in detail

CASE REPORTS

CASE I. Mrs. C. aged 41 years, complained of frequency and nocturia for 7 months (June, 1932). A cystoscopic examination on December 28, 1932, showed the bladder to be small and contracted with a capacity of 100 cubic centimeters. There was edema about the ureteral orifices. The wall of the bladder was reddened. The right kidney was loaded with pus which

was positive for tuberculosis. The left kidney showed 5 to 10 white blood cells per high dry field. The acid fast test was negative. The phthalein test showed some diminution of function on the right side. The total function was 43.5 per cent in one half hour. Bilateral pyelograms revealed caseocavernous tuberculosis of the right kidney and were suggestive of some involvement at the upper pole of the left kidney (Fig. 1).

A right nephrectomy was done on February 1, 1933, and the pathological report showed tuberculosis of the kidney.

The patient's postoperative course was uneventful except for a small hematoma in the posterior angle of the wound which was drained adequately. At the time of discharge, there was no elevation of temperature. There was a small sinus of the posterior angle of the wound, draining very little. The phthalein test showed first hour 2 per cent, second hour 30 per cent, total, 32 per cent.

The patient was readmitted on October 10, 1933, complaining of marked urgency and frequency so that she had to sleep on a bedpan. There was constant severe pain in the lower abdomen. The symptoms had been worse since nephrectomy. The urine was cloudy. There had been no loss of weight and no respiratory symptoms.

The blood count showed red blood cells, 5.1 million; hemoglobin, 95 per cent; blood pressure 155/80. The urine was cloudy without albumin or sugar but was loaded with white blood cells. Phenolsulphonphthalein test on October 20, 1933, showed first hour 20 per cent, second hour 15 per cent, total, 35 per cent.

Fig. 7 Excretory urogram (5 minutes) of the first patient a year after uretero-intestinal implantation.

On October 9, 1933, transplantation of the left ureter into the rectum was done under spinal anesthesia with gas and oxygen. The patient's blood pressure was 60/38 at the beginning of the operation after the spinal anesthesia and 104/54 at the end of the operation. She left the table in fair condition. Her systolic blood pressure was 70, one half hour after operation. The patient responded to glucose administered intravenously.

Operative procedure. An abdominal incision was made slightly to the left of the midline. The ureter was exposed (Fig. 2) by dissecting up the peritoneum above the brim of the pelvis. The peritoneum then was opened in line with the abdominal incision. The intestines were packed off. The peritoneum was slit as near the pelvic colon as possible and the ureter drawn through this opening (Fig. 3). A small longitudinal slit was made in the ureter high in the area of the peritoneal flap (Fig. 4). A No. 6 catheter was put through into the ureter. The distal end of this catheter was brought out through the abdominal wound behind the peritoneum (Fig. 5). Urine was seen to trickle out from the catheter. The ureter was implanted at the selected area in the bowel, Coffey's technique III being used. Drains were placed retroperitoneally (Fig. 6) and the wound was closed with retention sutures of wire.

The catheter drained well. On October 23, a catheterized specimen of urine showed 75 white blood cells per high dry field, 7 red blood cells per high dry field, and a few rods. The urine was alkaline. The ureteral catheter was removed on November 1; the urine was all draining through the wound. The stool was soft and formed. The patient began passing urine by rectum 18 days after the implantation, and, within 6 days, the urine was passed entirely by rectum.

The patient was discharged on November 23, 1933, afebrile, and with all the urine being passed by rectum; the bowel movements were regular. The wound was well

Fig. 8 Excretory urogram of the second patient 2 weeks after operation. The left kidney and ureter show normal function and appearance; the right, poor function and dilatation. The rectum and pelvic colon are outlined.

healed except for some infection at the lower end. The pain in the bladder was relieved. She has been seen several times and remains well and comfortable (1 year). Figure 7 shows the last excretory urogram.

CASE 2. Mrs. L. B., aged 3 years, entered the hospital on October 5, 1933. There had been three previous entries, two in May and a third in June, 1933. At the time of the first admission, a diagnosis of epidermoid carcinoma of the vagina had been made and the subsequent entries were for the purpose of X-ray and radium therapy. This consisted of approximately 3000 milligram hours of radium and 10 X-ray treatments. Her progress had been followed closely in the Women's Clinic.

Since July 1933 she had had a foul vaginal discharge. Part of the severe lower abdominal pain had been relieved by X-ray therapy but had recurred with increased intensity several weeks before the present admission. The pain was continuous, was made worse by exertion, and seemed most severe at night. It involved the right lower quadrant of the abdomen, the back and the right hip. The patient was still able to be up and to do part of her housework. Moderate bleeding from the vagina over a period of 3 to 4 hours occurred on October 13. She developed urinary frequency and nocturia four or five times.

The physical examination was essentially negative except for the local condition. The abdomen showed normal contour. The panniculus was fairly fixed. There was an old, well healed suprapubic scar. No masses were palpable. There was considerable tenderness over the entire right

Fig. 9 The left ureter and kidney of the second patient. A, Shows the ureteral opening in the bowel. B, The kidney is neither infected nor its pelvis dilated. The entrance into the intestine appears to be direct and not oblique.

side of the abdomen. The liver edge was palpable at the costal margin. There was tenderness to pressure over the right sacro-iliac joint. On pelvic examination the vaginal vault was found to be contracted. The cervix was small. The area of the right vaginal wall was puckered and relatively well healed. Because of this fixation, nothing else could be felt beyond it. On rectal examination to the right, the parametrial region was found to be filled with a fan-shaped mass which extended outward and backward to the wall of the pelvis. Pressure on this region caused pain. The rectal lumen was not appreciably encroached upon. The blood pressure was 110/70.

The laboratory findings were as follows: blood count red blood cells, 4,100,000; white blood cells, 4,800; differential polymorphonuclears, 68 per cent; small lymphocytes, 30 per cent; large lymphocytes, 5 per cent; eosinophils, 4 per cent; mononuclears, 6 per cent. blood Wassermann test, negative; urine, negative. X-ray examination of the pelvis on October 25 showed no evidence of metastases to the bone.

On January 3 a laparotomy was done by Dr. Lynch for the purpose of exploration, the release of adhesions, and a right salpingectomy. Palpation of the parametrial region revealed that on the right side a mass extended outward from the vaginal vault toward the sides of the pelvis. This did not seem quite to reach the pelvic wall. It was firm and very slightly movable. The left parametrial connective tissue was soft with no evidence of growth. No glands could be palpated in the pelvis. Because of the patient's youth, it was felt that it would be wise to attempt to remove the entire uterus, upper vagina, and bladder. This of course could not be done without preliminary transplantation of the ureters. The writer was called in to complete this part of the operation and a bilateral ureteral transplant to the sigmoid was done. The Coffey technique III being used, supplemented by bilateral ureteros-

Fig. 10 Drawing of the successful implantation on the left side in Case 3 of 8 months duration.

tomy with extraperitoneal drainage by catheter as in Case 1.

The patient's postoperative course was rather stormy. She developed a fecal fistula through the wound and then an infection of the wound. Her temperature continued to rise to 38 and 39 degrees C. for many days.

On January 12, excretory urograms showed a normally functioning left kidney but hydronephrosis and hydro-ureter with a poor function for the right kidney (Fig. 8).

On January 13 a right nephrectomy was done. Considerable pus was found in the retroperitoneal area immediately surrounding the kidney and down the course of the ureter. The kidney appeared to be large. When opened the pelvis was filled with pus. Microscopically multiple cortical abscesses of the kidney with chronic pyelitis and ureteritis were found.

After irrigation and debridement of the wound, the patient's condition rapidly improved and the temperature returned to normal. The kidney incision was almost healed at the time of discharge however thick, grumous foul smelling material continued to ooze from the midline

Fig. Photographs showing the kidney, ureter, and a portion of the pelvic colon removed at autopsy in the third patient. A, The badly infected kidney and the marked arteritis above the point at which the retention catheter was inserted. B, A closer view of the ureter.

suprapubic incision. The fistulous tract was extremely small. Pelvic examination on February 6 showed the vaginal mass to have increased markedly in size and to occupy practically the entire right lateral vaginal wall. Rectally it extended backward and to the lateral wall of the pelvis. Pressure upon it produced marked pain. The growth was obviously beyond any possibility of further surgery. Pain from the right pelvic region required repeated doses of opiates for relief.

At the time of discharge on February 16 the patient's appetite had returned, she had begun to gain weight and she was strong enough to sit in a chair for a short time each day.

After leaving the hospital she was comfortable except for pain in the right lower quadrant requiring relief from 1 to 5 grains of codeine two or three times daily. She reentered the hospital on July 31, 1934, because of four severe hemorrhages from the vagina. These recurred in spite of vaginal packs, and the patient died on August 10.

Autopsy showed numerous fine adhesions between the omentum and the abdominal scar. The omentum was adherent in the pelvis. Omental fat was thin and yellow. There was no free fluid. There were numerous adhesions in the right kidney fossa and about the cecum. There was a small stump of appendix, 1 centimeter long, covered by adhesions, through which the cecum was pulled medially toward the base of the mesentery of the ileum.

Kidneys. The right kidney was absent. The left kidney was freely movable and surrounded by a thin layer of perirenal fat. It weighed 180 grams and was somewhat pale but possessed normal markings. The cortex was 0.7 centimeter thick and the pyramids were normal. The pelvis was about normal in size but the wall was fibrotic and thickened to 0.2 centimeter. The ureter was anastomosed to the sigmoid in the pelvis, an end-to-side anastomosis, which was patent through a collapsible opening which easily admitted a 3 millimeter probe. The

ureter entered the sigmoid at about a right angle and the union was very firm (Fig. 9A and B). There was no excess ureter extending into the bowel. The ureter was somewhat dilated, just above the anastomosis, measuring 0.6 centimeter in diameter for about one-third of the distance, above which it was 0.4 centimeter in diameter. The wall was slightly thickened, uniformly. At the pelvic brim the ureter was adherent to the tumor mass but was not visibly constricted nor invaded (Fig. 10).

There was a hard nodular mass involving the posterior two-thirds of the sigmoid. This was most extensive on the ventral wall. It was thick, fixed, had a necrotic ulcerated surface and discharged a foul serosanguineous exudate. The cervix was entirely eroded or replaced by the tumor. The neck of the uterus was likewise eroded and replaced, tumor tissue extending well into the body of the uterus, the lumen of which was obliterated by the growth. The tumor mass had invaded the bladder wall extensively on the vaginal and uterine surfaces.

CASE 3. Mrs. Y., aged 68 years, had her first attack of hematuria 5 years before entry. The attacks recurred with increasing frequency, becoming severe 3 to 4 months ago. A large tumor of the bladder was found at cystoscopic examination 2 months ago. This was fulgurated three separate times without much regression. On January 6, 1934, the right ureter was transplanted to the sigmoid, with a ureterostomy drain, above the implant, which came out through the midline incision extraperitoneally. The bladder was removed. The patient was in poor condition in the surgery and the left ureter, which had been partially obstructed by the tumor in the bladder, was brought to the skin at the end of the operation. The patient excreted not more than about 700 cubic centimeters of urine each 24 hours. She developed tympanites and paralytic ileus with fecal vomiting. A nasal tube was used for 3 or 4 days, with constant suction, fecal material being aspirated. The patient failed rapidly during the last 5 days, developing tracheitis and terminal bronchopneumonia. On postm-

Fig 12 a, Photomicrograph of a serial section showing the right ureter entering the sigmoid in Case 3. b Higher powered photomicrograph showing the inflammatory reaction. The ureter shows atrophy and necrosis at the point of entrance through the sigmoid. a subacute inflammatory reaction is seen extending in all the coats of the bowel.

n trogen was 62.5. 2 days before death. Death occurred on January 19, 1934.

The autopsy (by Dr. Biskind) was limited to a slight lengthening of the midline abdominal incision, which showed very little healing and much unduration as the result of an inflammatory reaction. The bowel showed a few loops plastered to the incision, forming a small pocket holding an inflammatory exudate. The pelvis was greatly distorted because of the absence of the bladder and, in this region, there were several hundred cubic centimeters of a thick purulent material which had collected in a pocket.

The gastro-intestinal tract was examined from the esophagus to the rectum, and aside from the local reaction around the sigmoidostomy there was little evidence of abnormality.

The left kidney weighed 160 grams and was surrounded by a firm, perirenal fat which showed evidences of slight inflammation. The left ureter was greatly dilated and bluish red in color. The surrounding peri-ureteral tissue likewise was involved by inflammation. This ureter led to the stab wound in the left lower quadrant, and passed along the brim of the pelvis near the end of the left broad ligament and left ovary into the abdominal wall. At this point a drain entered the ureter, and this ureterostomy apparently had been functioning. On cut section the left kidney showed an acute purulent reaction in the pelvis, extending into all the calyces and into the parenchyma. The kidney itself was relatively large and soft. The capsule could be stripped. The demarcation between cortex and medulla was not clearly evident.

The right kidney was likewise greatly enlarged and was surrounded by perirenal fat showing inflammatory changes. This ureter was greatly enlarged and similar to the left ureter. The ureter below the drain was relatively small and contracted, and did not show the inflammatory reaction above noted (Fig. 12A and B). The sigmoid, when opened showed a tag of necrotic ureter extending into the lumen. Serial sections were made of this juncture because very

little could be made out grossly (Fig. 12). The right kidney was slightly larger than the left, weighing 300 grams, and showed all the changes found in the left kidney. In addition there were multiple, small, scattered cortical abscesses.

The parenchyma of the right kidney was distorted by a marked purulent inflammatory reaction extending up from the pelvis. There were many small scattered abscesses throughout the cortex and medulla. A few old scars of an arteriosclerotic nature were present. The acute reaction extended into the capsule. The cortical abscesses and the marked reaction were not seen in the left kidney but it showed an acute, gangrenous purulent pyelitis with the inflammation extending into the adjacent fat. The right ureter above the ureterostomy showed a zone of acute necrosis superimposed on a chronic inflammatory reaction, and there was an acute peri-ureteritis. This ureter below the ureterostomy was undergoing atrophy and necrosis probably of an infarcted nature. Serial sections were made showing the right ureter entering the sigmoid (Fig. 12). The ureter showed atrophy and necrosis, and at the point of entrance through the sigmoid, a subacute inflammatory reaction was found extending in all the coats of the bowel with a localized peritonitis. The formation of scar tissue had begun in this region.

SUMMARY AND CONCLUSIONS

The postoperative course of the first patient, and the perfect implantation on one side with normal ureter and kidney (Figs. 9 and 10) found at autopsy 8 months after operation in the second patient, encourage the belief that extraperitoneal drainage by ureterostomy and ureteral catheter in conjunction with implantation of the ureter into the bowel by the hidden perforating suture

1. C. C. is a method by which bilateral implan-

tion would be made. The catheter gives free drainage until the suture cuts through. Opposed to this are the imperfect drainage and acute pyelonephritis which was present on the right side in the second patient and the finding at

autopsy of the acute ureteritis and the necrosis above the ureters only and of aneurysm infection below in the third patient, a complication which was apparently caused by the retention catheter. This method, therefore, cannot be recommended.

ANTERIOR GASTRO-ENTEROSTOMY BY THE SHORT LOOP METHOD

Rara-Steady Clinic

PALLIATIVE operations often are indicated in cases of obstructive lesions of the stomach. Posterior gastro-enterostomy has long been the operation of choice in such cases. If its successful completion is not possible, however, some other method must be used. The classical anterior gastro-enterostomy is a poor second choice on account of the frequent complications which follow its use, namely obstruction and ulceration at the site of anastomosis or in the intestine near the anastomosis. Enterostomy in conjunction with anterior gastro-enterostomy lessens the possibility of obstruction but complicates the physiology of the intestinal tract and lengthens the operative procedure in a case which may be already a bad risk. We wish to present a short loop method of anterior gastro-enterostomy which offers the advantages of the posterior gastro-enterostomy and avoids some of the disadvantages of the classical anterior operation.

Recently in a case of an irremovable obstructive carcinoma involving the mid portion of the lesser curvature of the stomach we found that the lesion had extended into the posterior wall to such an extent that a posterior gastro-enterostomy was not possible. The anterior wall was free from infiltration. It was decided therefore to do an anterior gastro-enterostomy but to make the anastomosis through the mesocolon by a short loop method and thereby avoid the usual long loop which would have to be drawn anterior to the transverse colon.

The stomach was separated from the transverse colon by ligating the gastric branches of the gastro-epiploic arteries of the stomach in the gastrotocolic omentum. This opened the lesser peritoneal sac and freed a major portion of the greater curvature. The transverse colon was then drawn through the abdominal incision and an opening was made in the transverse mesocolon. The anterior wall of the stomach above the obstruction was drawn through the opening in the transverse mesocolon and one part of a light gastro-enterostomy clamp was applied. The stomach proximal to the clamp was sutured to the margins of the mesocolon so that after the colon fell to its normal position these sutures rotated the anterior wall of the stomach. In this way the portion which was superior was brought into a lower plane and the portion to be anastomosed was held

in the new position. The jejunum just distal to the ligament of Treitz was located and placed in the other portion of the gastro-enterostomy forceps. Then the antiperistaltic anastomosis was completed. The upper portion of the jejunum midway between the mesenteric and the antimesenteric border rather than the antimesenteric segment was the portion placed in the clamp. This avoided a rotation of the intestine in the axis of its lumen following anastomosis. Finally the anterior wall of the stomach above the anastomosis was sutured to the transverse colon along the line of the gastrotocolic omentum from which the greater curvature of the stomach had been separated.

The patient made an uneventful recovery. He had no nausea or vomiting and to date, 8 months after operation, has had no untoward symptoms. Deep X-ray therapy was instituted 3 weeks after the operation was performed.

The technique of the operation by steps is as follows:

1. An upper abdominal incision following the method advocated by Sloan is used.

2. The greater curvature of the stomach is freed from the transverse colon by ligating the gastric branches of the gastro-epiploic arteries directly below the chosen site of anastomosis, thus giving entrance to the lesser peritoneal cavity (Fig. 1).

3. The colon is drawn out of the incision, tensing the mesocolon which is opened between the colic vessels sufficiently to allow the anastomosis to be made.

4. The anterior wall of the stomach is sutured to the upper margin of the opening in the transverse mesocolon with interrupted chromic catgut sutures placed about three-quarters of an inch apart (Fig. 2).

5. The anterior wall of the stomach is drawn through the opening of the mesocolon and held by a light gastro-enterostomy clamp. Then the remainder of the opening in the transverse colon is closed by suturing it to the stomach proximal to the clamp.

6. The jejunum is located just distal to the ligament of Treitz and a short loop is placed in the anastomosis clamp in position for antiperistaltic anastomosis (Fig. 3A).

7. The anastomosis is closed by three continuous sutures of chromic catgut, the first layer

Fig 3 Short loop anterior gastro-enterostomy. A Short loop of jejunum placed in anastomosis clamp. B Relative position of jejunum to stomach after completion of operation. C Appearance of completed operation from below—similar to posterior gastro-enterostomy except that the anterior instead of the posterior wall of the stomach is anastomosed to the jejunum

including the serosa and the muscularis the second layer including the serosa muscularis and submucosa and the third layer including all three layers as an over-and-over haemostatic stitch (Fig 3 B and C)

8 The area on the colic side of the gastrocolic omentum first detached from the stomach is then sutured to the anterior wall of the stomach

9 The abdomen is closed without drainage

CONCLUSION

A technique for a short loop method of gastro-enterostomy is presented as a substitute for the

classical anterior gastro-enterostomy in those cases in which a posterior gastro-enterostomy is not technically possible

We believe that the method which is here presented offers the advantages of a short loop posterior operation and that it avoids the disadvantage of the possible complications which usually accompany the long loop anterior gastro-enterostomy

MESENTERIC CYSTS¹

A BRIEF DISCUSSION AND REPORT OF THREE CASES

CHARLES S. ROLLER, M.D. F.A.C.S. COLUMBIA, CALIFORNIA

PROBABLY the first cyst of the mesentery was described by Benivieni, a Florentine anatomist of the sixteenth century. He discovered the tumor at autopsy and recorded it as an anatomical curiosity. The lesion is sufficiently uncommon to arouse considerable interest whenever encountered. Possibly about 500 cases are recorded in the literature. In 1932 in a very fine review Warfield found a total of 129 reported cases since 1920. Carter in 1921 estimated that between 200 and 300 cases were recorded, while Flynn in 1930 thought the literature contained no more than 300 cases at the most. Judd states that in 820,000 admissions to the Mayo clinic hospitals, only 25 cases of mesenteric tumor were found and only 8 of these were cysts. Therefore in this clinic the incidence of mesenteric cyst was less than 1 per 100,000 admissions, while a tumor of some kind was found in the mesentery in 1 of some 35,000 cases. The Massachusetts General Hospital has a record of only 6 cases from 1900 to 1926. The University of California Hospital has a record of 1 cyst and 1 tumor of the mesentery in 93,511 admissions, since 1906. The Children's Hospital Los Angeles, has 3 cases recorded all in females, and all occurring in the last 3½ years, in a total of 12,425 admissions during the same period. Los Angeles General Hospital has a record of 1 case in 188,921 admissions in the last 5 years. Lane Hospital reports 3 cases from 1911 to 1933 in approximately 77,000 admissions. The New Harborview Hospital Seattle has no record of a mesenteric cyst in 27,000 admissions, and approximately 12 surgeons and pathologists in Seattle have no record of a case.

Warfield found in 129 cases the sex distribution as follows:

	Cases
Female	7
Male	37
Unknown	8
	29

Nine of the cases were in infants under 1 year of age and 21 were in children from 1 to 10 years of age. The age group from 30 to 40 showed the greatest incidence, 24 cases. I have encountered 3 cysts of the mesentery on my own service of

about 900 surgical admissions, during the last 2½ years or 1 in every 300 cases. Two were cases of intestinal obstruction, with the cysts as the etiological cause, and the other was a small cyst, possibly symptomless encountered during an operation for recurrent appendicitis. All occurred in males, all were undiagnosed before operation, and all were found in the mesentery of the ileum less than a meter from the ileocecal junction. In the literature, women seem to be affected about twice as often as men. Statements appear that the diagnosis is never made before operation. However correct pre-operative diagnoses were made by Haworth, 1920. Bertolini, 1921 and later by Alot in 1927 and Flauod 1930 and others.

The history of these cysts has been well divided into four periods: (1) 1707 to 1850 when the lesion was only discovered at autopsy (2) from 1850 to 1880 when an occasional cyst was operated upon, but there were no recoveries (3) from 1880 to 1900 when operation was beginning to be followed by a few recoveries and (4) from 1900 on when the condition was becoming definitely known, was more successfully treated, and occasionally diagnosed before operation. Possibly it is the rarest tumor of the abdomen. It may occur at all periods of life from infancy to extreme old age. Textbooks refer very briefly or not at all to the condition, and many surgeons of wide experience have never encountered a case.

The cysts may vary in size from less than a centimeter in diameter to truly huge tumors that fill the entire abdomen; thus they may be too large or too small to diagnose easily. About 70 per cent appear in the mesentery of the small bowel and the remaining 30 per cent are found in the mesentery of the large bowel or other mesenteries. Warfield's 129 cases were located as follows:

	Cases
Small bowel mesentery	61
Large bowel mesentery	50
Gastrohepatic mesentery	
Appendix mesentery	3
Unknown or unstated	5
	129

They are usually oval, round or bosselated, may be unilocular, bilocular or multilocular and

may be filled with chyle clear serous fluid, hæmorrhagic fluid clotted organized blood or other material. Some contain cholesterol crystals. Many times the walls are greatly thinned and any lining membrane the cyst may have possessed earlier has been destroyed through pressure atrophy. Likewise the entire wall may give no definite clue as to the origin of the lesion. Often times the contents are no more valuable as far as etiology is concerned.

DEFINITION

A true mesenteric cyst must occur between the leaves of the mesentery or under the serosa of the gut, and must not be a retroperitoneal cyst, although it may have originated from sequestered material which has migrated from retroperitoneal embryological organs to a position between the leaves of the mesentery. Cysts occurring retroperitoneally or under the peritoneum of the abdominal wall may have a similar origin but are not mesenteric cysts by location. Cystic malignant disease of the mesentery should be classified under malignant tumors as very rarely is there a record of a mesenteric cyst becoming malignant yet, Deaver suggests that such is a possibility as branchial cysts sometimes become malignant.

ETIOLOGY AND CLASSIFICATION

It seems impossible to determine accurately the etiology of many of these cysts, and so many classifications have been offered that the affair is confusing. Since quite a number occur in young children it is fair to assume that many of them are embryological in origin. A classification follows.

1. *Embryocystomata or embryonic inclusion tumors* (a) Those derived from sequestered remnants of the wolffian body or its duct, or the müllerian duct. In other words it seems possible that portions or remnants of the urinary or genital embryological organs could become detached migrate to a position between the leaves of the mesentery, retain or develop a blood supply, and develop into cysts. Pararenal cysts in all probability have origin from the wolffian body but nevertheless they retain their position near the kidney.

b Cystic dermoids and teratomata. The genital glands in both sexes develop behind the peritoneum as do other of the abdominal organs and the same theory holds true.

c. Dermal inclusions. This does not seem to account for many cysts although a dermal sebaceous cyst has been reported in the mesentery

by Swartley in 1927. Bartlett, in 1923 suggested this as an origin.

d. *Enterocystomata* or cysts developing from misplaced intestinal tissue. Here sequestrations from the intestine, fetal intestinal diverticula, or from the omphalomesenteric duct (vitelline) become displaced to positions between the leaves of the mesentery. In this manner cysts from intestinal remnants may occur anywhere along the digestive tract, while those from the vitelline duct occur principally in the mesentery of the ileum near its termination. Meckel's diverticulum represents the failure of the intestinal end of this same duct to become completely obliterated. Umbilical cysts may represent the failure to close of the other end of this duct. Miller reports a case of a 4 day old baby in which the wall of the cyst was, in one portion, directly continuous with the wall of the jejunum and the histological structure of the cyst wall resembled rather accurately the wall of the bowel. Here seems proof of a mesenteric cyst that owed its origin to sequestration or diverticulation of embryonic intestine. Minute intestinal diverticula and cysts are not infrequently found in rabbits.

2. *Chylous cysts* Ewing suggested that these cysts were chyle angiomata, which arose either from congenital or acquired obstruction to the mesenteric lymphatics and lacteals, carrying the chyle from the intestines to the receptaculum chyli. However Dowd thought that the chylous nature of some of these cysts was due to an effusion of chyle into a preformed cyst, especially since the very rich anastomosis of the mesenteric lymphatics seems to preclude that obstruction to even many channels would form a cyst.

3. *Bacterial or parasitic cysts* It seems possible that the necrosis and liquefaction in the enlarged mesenteric lymph glands of tuberculous, typhoid fever or bacterial infection of other nature might result in cyst formation. There is some evidence to support this. Parasitic, hydatid, or echinococcus disease has been responsible for cystic change in the mesentery.

4. *Traumatic cysts* These may be filled only with blood and result from operative or other trauma to the mesentery, resulting in hemorrhage between its layers with or without subsequent serous change. Genkin in 1928 reported a chylous cyst in the mesentery formed around a gauze sponge left in the abdomen during a previous operation.

5. *Angiomata of blood or lymph vessels* Very few cysts of the mesentery seem to be true lymph or hæmangiomata, and probably only a few cysts have this origin. However, in the past, competent

Fig. Case 1. Drawing of cysts as they appeared in the abdomen and also on cross section, showing the mechanism of the obstruction and the recent perforation of the ileum into one locule converting it into an abscess.

authorities have thought many of these cysts were a form of lymphangioma.

6 *Gas cysts*. Gas cysts are rare, usually symptomless, and nothing definite is known as to etiology. They may be multiple. Possibly they do not belong in a classification of this sort, as they seem fundamentally different.

SYMPTOMS

There are no definite pathognomonic findings applicable to the general run of cases. Most of them must be symptomless early in their development, and even until they are quite large, when the patient may note enlargement or a growth in the abdomen only. Usually the provisional diagnosis before operation is not correct.

However a rounded, freely movable, cystic, nontender abdominal mass, should suggest the possibility of a mesenteric cyst. According to several writers, the mobility is most striking in the transverse direction. Sometimes a belt of resonance can be percussed over the tumor where the intestine passes over it. Ruling out connections with the lumen of the bowel and other findings made with the barium meal or enema and fluoroscopy and films, should be valuable. Pressure from a cyst may give symptoms, depending upon which intra-abdominal organ it is encroaching upon. In one of my cases initial urinary symptoms were possibly caused by pressure of the cyst upon the urinary bladder. When complications arise the symptoms may be almost anything.

Fig. 2. Case 1. Wall of smaller locule (contents sterile) showing an organized granulation tissue and some large endothelial lined spaces.

Fig. 3. Case 1. Wall of larger locule (abscess due to intestinal perforation) showing inner surface which has a fibropurulent exudate.

are usually very pronounced and about 40 per cent of all complications are intestinal obstruction, either acute chronic, or intermittent in type. When acute complications ensue, the differential diagnosis would have to include almost every cause for the acute abdomen so varied may be the manifestations. It is well to bear in mind that an etiologically obscure but definitely acute abdomen should be explored without much wasted time. The main point, so far as the pre-operative diagnosis is concerned is to bear in mind the possibility of a mesenteric cyst.

PROGNOSIS

Atchley states the mortality to be 35 per cent for the cases as a whole. As previously mentioned intestinal obstruction brings about 40 per cent of the cases to medical attention and in this group the mortality is variously stated to be from 30 to 50 per cent. Warfield, in his 129 reported cases gives a known more or less immediate mortality of 20 per cent. In 23 of this series of cases the patient was able to leave the hospital but no follow up record was available. Of course the prognosis depends largely upon the time of diagnosis and operation type of operation found necessary size location attachments and complications present and the age and general condition of the patient.

COMPLICATIONS

These in the main are intestinal obstruction with or without gangrene of the bowel wall vol-

ulus (as present in one of my cases) intussusception adhesions or attachments to organs hemorrhage into a cyst, rupture of a cyst into the abdominal cavity rupture of the cyst into the bowel or vice versa causing acute inflammation and abscess formation in the cyst (as in another of my cases) perforation of an infected cyst with

Fig. 4. Case 1. Shows the granulomatous reaction in the wall of the small intestine near the perforation. The crystals represent cholesterol, probably due to inspissation or fat necrosis.

Fig. 5. Case 3. Showing tumor and volvulus and mechanism of the intestinal obstruction; also removed specimen.

peritonitis, ileus, and gastric dilatation and the complications that may ensue after abdominal surgery.

TREATMENT

This part of the subject seems to be rather definitely settled. The treatment is purely surgical, and in order of desirability is as follows:

1. Enucleation, if possible, without jeopardizing the viability of the gut by too much damage to its blood supply. This procedure is accompanied by about 9 per cent mortality.

2. Enucleation or resection accompanied by removal of a portion of bowel and anastomosis. Mortality is 25 to 30 per cent.

3. Manipulation or incision and drainage. This method should be used only when it is out of the question to do otherwise due to size, location, adhesions, or poor condition of the patient. The mortality is about 16 per cent. Cure is not always accomplished by this method and drainage persists for some months as a rule.

4. Aspiration seems to me to be a very unsatisfactory method of treatment. It has its place only as a means of diagnosis (with abdomen open) or to reduce the size of cyst preparatory to removal.

CASE REPORTS

CASE 1: Master A. P., white American boy aged 6 years, was referred to me on February 6, 1933, with the following history: He had pain in the right side of abdo-

men, nausea, vomiting and obstipation. The child had gone to school the previous day and returned home in the afternoon complaining of not feeling well all day. He complained of sharp pains all over abdomen, mostly in the right side. Nausea soon developed accompanied by vomiting, which continued throughout the night. A physician was consulted the next morning who diagnosed acute appendicitis and advised taking the child to the hospital at once. This was not done until 6:30 the same evening, after the child had been given castor oil and enemata, with no results other than to increase the pain and vomiting.

The past history was uneventful except for measles and for the fact that during the last 6 months at intervals of 3 or 4 weeks, the child had had sudden attacks of abdominal pain, with vomiting, lasting only a few hours, after which the child again felt perfectly well. The mother says the child was constipated before these attacks and that laxatives and enemata gave relief. She thinks he had no elevation of temperature.

Physical examination revealed a child acutely ill. He lay in bed with thighs flexed, and cried with pain if moved. The abdomen was moderately distended and on inspection it seemed to be more prominent in the right lower portion than elsewhere. The abdomen moved very slightly with respiration in the upper portion, and palpation determined the presence of a round, exquisitely tender, non-movable mass as large as a baby's head in the right lower quadrant. The right side of the abdomen was rigid, to such a degree that it was impossible to outline the mass accurately. It did not involve the kidney region. It could be felt by rectal examination. Except for evidences of dehydration, the rest of the physical examination elicited normal findings.

Laboratory examination of voided urine showed color amber, clear reaction, acid specific gravity 1.021; albumin and sugar negative; plus acetone; microscopic examination normal.

Blood examination showed hemoglobin 80 per cent Sahli, red blood cells, 4,700,000 white blood cells, 20,000 polymorphonuclears, 84 per cent.

Diagnosis (1) Abdominal tumor with intestinal obstruction and peritonitis (2) appendiceal abscess with obstruction and peritonitis

Operation. After adequate preparation the abdomen was opened, under nitrous oxide-oxygen-ether anesthesia. Dilated coils of intestine, a bloody serous exudate, which was cultured, and a bilocular cystic, bluish tumor arising from the mesentery of the ileum about 20 inches from the ileocecal valve, and freely movable, were found. The tumor was easily delivered into the wound. Each locule was the size of an orange, about 9 centimeters in diameter and one was covered with a glistening peritoneum and the other with a red inflamed peritoneum. The neck was broad and connected the two locules just under the mesenteric border of the gut in such a manner that the tumors so compressed the lumen of the ileum that almost complete obstruction existed. The appendix was normal.

An attempt was made to enucleate the tumors, but in so doing the inflamed locule was punctured in an area adherent to the intestine, through which the ileum had perforated into the cyst, forming an abscess within the cyst, and a few drops of foul smelling fecal material escaped. The rent was at once closed by suture and a resection of 3 inches of ileum cysts, and a V of mesentery done with end-to-end anastomosis following. Because of rupture during operation a small Penrose drain was inserted down to the anastomosis and the abdomen closed in layers. The patient made an excellent recovery. There was no vomiting, beyond the first 12 hours after surgery. Fluids were maintained by hypodermoclysis of normal saline and 5 per cent glucose retention enemata for the first 48 hours. The drainage from the abdomen was only moderate, the drain was removed on the third day after operation. The bowels were controlled easily with mineral oil. A temperature rise occurred on the sixth day after operation from a small abdominal wall abscess and on the twenty second day from an upper respiratory infection. Both were easily controlled. The patient left the hospital on the thirty-first day after operation, with the wound completely healed and the bowels regular without laxatives. He has been followed at intervals for over a year. It is growing rapidly, doing well in school and has no complaints of any kind. No incisional hernia developed.

Pathological diagnosis by Dr Edwin I Bartlett. Un differentiated cysts of the mesentery.

This tumor should have been easily movable but the acute abdomen and obstruction rendered the abdomen so spastic that this point could not be made out before operation. Had not the perforation into one cyst locule been present we probably could have performed the less dangerous operation of enucleation instead of resection with anastomosis of bowel. Probably the perforation occurred the day or night before operation, producing the fever leucocytosis and swelling in the cyst locule, and much more complete intestinal obstruction than the child had had with the previous attacks.

The contents of one locule were distinctly serous. The contents of the locule into which the gut had perforated were cloudy purulent, and fecal smelling. Cultures of this fluid gave abun-

Fig 6. Case 2. Representative section of the cysts and also of the adjacent bowel, showing extravasated blood in the mesentery and extending to muscularis and mucosa of the damaged loop of bowel.

dant growth of intestinal organisms, while cultures of the other locule were negative. The contents were not chyle like. Because of the location this could have been a cyst originating from either an intestinal diverticulum or from the omphalomesenteric duct or from lymphatic ducts or lymphangioma.

CASE 2. Mr B C M, adult white male, single, aged 53 years, was admitted to the hospital at 2 15 p m on August 19, 1933. He had generalized intermittent abdominal pain, vomiting, obstipation, urinary difficulty and persistently distended abdomen for the past 48 hours. He began feeling ill 3 days ago and could not pass urine. He went to a doctor who catheterized him easily and obtained only a few ounces, after which he had been able to void small amounts. Since then he had not been seen by a physician until just before admission to the hospital. Two days ago the pain became worse and patient started to vomit. Several enemata and a laxative failed to move the bowels. He has had considerable abdominal pain of an intermittent character which he says extends over the whole abdomen and he thinks it is worse about the umbilicus and over the bladder region. He feels gas moving about in the abdomen and at these times the pain is most severe. He has vomited persistently for 48 hours and the bowels have not moved. He did not vomit any fecal smelling material.

Patient has always been well and strong except for a right inguinal hernia repaired 15 years ago and an appendectomy performed 12 years ago. The hernia has not recurred since and he left the hospital in 12 days after his appendectomy with the wound fully healed. He has noted a gradual increasing constipation for the last few years, but thought little of it. He has had no urinary difficulty whatsoever until the present illness.

Fig. 7. Case 3. Drawing showing the size and location of the cyst, the two calcified mesenteric glands and the appendix.

The family is negative as far as the present illness is concerned.

Physical examination. Patient is obviously very ill. The skin, tongue and mucous membranes are dry and delirious pulse 94 per minute, temperature 99.8 degrees F. and respirations 24 per minute. The heart seems slightly large to percussion and a non-transmitted murmur is heard at the apex. Tonal quality is good and there is no evidence of decompensation. Blood pressure is 124/72. Patient vomited about a pint of bile stained foul stomach contents during the examination. The abdomen is greatly distended and tense, the percussion note is tympanic throughout. There is moderate tenderness and muscle spasm over the lower abdomen, and no masses or organs are palpable, owing to the distention. With the stethoscope an occasional peristaltic movement can be plainly heard, corresponding to the patient's spasms of pain. The bladder is not distended. Catheterization is easily done and yields about 5 ounces of clear dark urine. The rectal examination reveals what appears to be distended coils of gut deep in the pelvis or a soft, only slightly tender mass. The prostate is small and sphincter tone good. The rest of the examination revealed nothing of note.

Laboratory examination showed the urine dark, clear in color, specific gravity 1.028, reaction, neutral, trace of albumin, no sugar, plus acetone. Microscopic examination showed an occasional hyaline cast, occasional pus and epithelial cells. The specimen was centrifuged.

Blood examination showed white blood cells, 8,000, red blood cells, 4,600,000.

Diagnosis. Acute intestinal obstruction, probably from adhesive bands about terminal ileum from previous laparotomy.

Procedure. Patient was put to bed, and several hours were spent preparing him for operation. He received 500 cubic centimeters of salt solution subcutaneously, enemas, without results, stimulants and gastric lavage. Under low spinal anesthesia laparotomy was performed. The entire abdomen was filled with tense, distended coils

of ileum, quite reddened in appearance, so we determined that the obstruction was quite low down. Inserting the hand into the pelvis a tumor mass was found deep down against the bladder and feeling cystic and lobulated. It was easily delinked into the wound. The tumor was seen to be a multilocular cyst of the mesentery of the ileum, about 24 inches from the ileocecal junction, 4½ times 2½ inches in diameter and with the cyst locules very closely encroaching upon the gut and one or two bulging past the antimesenteric border. There was complete volvulus or torsion of the cyst and involved intestine, i.e. one twist of the mesentery causing a complete intestinal obstruction and a pregangrenous condition of the involved gut. Fortunately the adhesions were not tight and very little of the mesentery was hemorrhagic and thrombosed. The distended coils of gut were so in the way that an ileostomy was done 8 inches above the obstruction, using a No. 6 catheter and by very gentle suction a great deal of liquid material and gas was removed. Resection of the cysts, about 5 inches of bowel and the injured mesentery was done followed by an end-to-end anastomosis. The abdomen was closed in layers about a small drain and the ileostomy tube.

The patient was returned to the ward in fair condition, blood pressure 100 systolic and fully conscious and rational. The ileostomy tube was allowed to drain every alternate hour the patient was digitized, 3000 cubic centimeters of normal saline was given subcutaneously per 24 hours and 300 cubic centimeters of 5 per cent of saline given intravenously the first 3 or 4 days. Retention enemata of 6 ounces of 5 per cent glucose were given every 4 hours. (Not only does this last supply fluid, but the irritation it causes in the lower bowel stimulates peristalsis higher up, and is of material aid in the after-care of a case of this kind.) There was considerable purulent drainage from the abdomen, and the drain was shortened daily and removed completely the fifth day after operation. The bowels were moved daily with a small enema. The first bowel movement unaided by an enema occurred on the sixteenth day after operation. The ileostomy tube was clamped off permanently on this day and was removed on the nineteenth day after operation. The fistula closed rapidly and the patient left the hospital on the twenty-eighth day after operation with his wound completely healed except for a non-draming granulating area at the site of emergence of the catheter. His general condition was good and his bowels were moving well on ½ ounce mineral oil twice daily. He was seen a week later feeling fine, wound completely healed, appetite and bowels were normal. This patient was last seen on December 20, 1933, about 3 months after operation when he had gained about 20 pounds in weight, and his bowels were regular without laxatives or mineral oil. He had no complaints.

Probably this cyst resulted from trauma to the mesentery possibly during the appendectomy 12 years previously. There is no history of other abdominal trauma. There is no proof that it is a hemangioma.

Diagnosis by Dr. Edwin I. Bartlett. blood cysts of the mesentery.

CASE 3. Mr. L. H. M., white American male, aged 46 years, was admitted to the hospital March 25, 1933. Patient complained of pain and discomfort in the right lower abdomen, at intervals for the past 3 years. About 2 years ago the patient began to be conscious days at a time of pain of an aching character in the right lower quadrant, aggravated by eating and working. He sometimes felt nauseated, but never vomited. After a few days the pain would leave and not occur for 2 or 3 weeks. The last few months the condition has been worse and he comes to the hospital for relief. There is no gall bladder pain, no ulcer

history no urinary symptoms, and the pain does not radiate. Patient admits having syphilis in 1906. He was treated at intervals until 1919 and since then the Wassermann reaction every year has been negative. No gonococci were noted. He has never been ill otherwise. He has always been a native of California.

The family history is negative for tuberculosis or chronic disease.

Physical examination temperature, pulse, and respiration were normal. Head and neck were negative, heart and lungs normal. The blood pressure was 130-84. The abdomen was flat, moved well with respiration, there were no organs or tumors palpable, and no rigidity, but very definite point tenderness to deep palpation over the appendiceal area. Rectal examination revealed only a few small hemorrhoids, a slightly enlarged prostate and good sphincter tone.

A plain film of the abdomen revealed normal kidney shadows, and in the appendiceal area and above the brim of the pelvis were two shadows, like stones, 3 by 1 and 1 centimeter in diameter, respectively. A barium enema revealed a normally filling and appearing large bowel, a competent ileocecal valve, and a poorly filling appendix which was not very movable and was very tender to deep palpation. The two shadows observed in the plain film, were seen about 3 inches above and a little medial to the appendix, and were freely movable, and not tender. We thought they were calcified mesenteric glands.

Spinal fluid and blood Wassermann reactions were negative. The urine was negative, the hemoglobin 82 per cent. Salih, red blood cells, 4,600,000 white blood cells, 6,900.

Diagnosis recurrent appendicitis, calcified mesenteric lymph glands.

Operation revealed a short, bulbous, chronically inflamed appendix, adherent to the cecum and ileum. The two shadows were found to be calcified lymph glands in the mesentery of the ileum about 3 or 4 inches from the ileocecal junction, one near the root of the mesentery the other nearer the gut. Between the two was a thin walled cyst, of the mesentery about 3 centimeters in diameter. The glands and appendix were removed. The cyst was shelled out, but in so doing the very thin wall ruptured, a colorless thin fluid escaped and the wall was subsequently lost, so that we were unable to study it. Convalescence was uneventful. The patient was discharged on the eleventh day after operation. He was last seen March 6, 1934, almost a year after operation. He has had a complete relief of symptoms. Crushed sections of the nodes revealed nothing but calcium. Pathological diagnosis of the appendix was normal. Only one cross section was examined, and the organ was not normal grossly. This cyst might have resulted from liquefaction of an infected lymph node, especially since on either side was a calcified node. Could the appendix have caused the lymphadenopathy? No other cause was found.

SUMMARY AND CONCLUSIONS

The first cyst of the mesentery was found at autopsy in the sixteenth century. The history of the tumors is divided into four periods. Possibly four or five hundred cases have been reported in the literature. It is probably one of the rarest of abdominal tumors. The etiology, correct classification and pathology are obscure. The mortality rate is higher than it should be and the diagnosis is uncertain before operation both

should be improved. Possibly if we would bear in mind the possibility of mesenteric cysts in obscure abdominal lesions we would diagnose more cases before operation. Complications are disastrous as a rule, often give the first symptom and thus obscure and cloud the diagnosis. Uncomplicated cases, and most cases taken early should have a relatively low mortality. Three personal cases are reported fully. All recovered. Two are known to be alive and perfectly well more than a year after operation, and the third was doing very well when last seen 3 months after surgery. Two of the cases were obscured by grave and serious complications and the third was a small cyst, possibly symptomless. The etiology was not determined exactly in any case. A possible classification of these lesions is presented. The subject is extremely interesting from the standpoint of etiology, symptomatology and diagnosis, and it should be emphasized that it be considered more often in the differential diagnosis of intra abdominal disease.

TERATOMA OF THE SPINAL CORD¹

PAUL C BUCY M.D. and DOUGLAS N BUCHANAN M.D. CHICAGO ILLINOIS

TERATOMATA of the spinal cord are among the rarest of tumors. The following case in which such a tumor was found is of casual interest because of the difficulty in differential diagnosis which it presented and because it so clearly illustrates the amazing ability of the spinal cord of a child to recover from severe compression.

CASE REPORT

R. B., onset with irritability and anorexia at 16 months of age, slowly developing paraplegia with pain in left ankle examination revealed a paraplegia without sensory change, lumbar puncture demonstrated a complete subarachnoidal block with From's syndrome. Lipiodol injected roentgenographic changes in lower dorsal and lumbar spine, operation at 2½ years of age removal of teratoma of spinal cord recovery.

R. B., unit No. 83815 male, was born on June 30 1931. He was referred by Dr. R. W. Carpenter of Geneva, Illinois, and first admitted on the pediatric service of the University of Chicago Clinica on June 8 1933 with complaints of "failure to gain weight and weakness of the left leg."

This child was the last of four pregnancies. The first pregnancy terminated in a premature birth, the infant died shortly thereafter. The second child was a "blue baby" and is at present alive and apparently well (although not examined) at 6 years of age. The third pregnancy terminated in an abortion. The remainder of the family history has no obvious relation to the condition of this child. R. B. was normal at birth and weighed 7 pounds, 4 ounces. Except for an attack of impetigo shortly after birth his infancy was uneventful. He walked at 1 year of age and weighed 21 pounds. There were no other illnesses.

In the latter part of October 1932 (age 16 months) he began to cry more frequently, became very irritable and it was difficult to get him to eat. At about the same time it was noted that the neck was becoming stiff. This persisted for about 6 weeks. He had no fever, there was no vomiting or diarrhea. This illness continued unchanged and in November he was confined to bed where he remained until March, 1933. During this period he was unable to raise his legs, but in March he began to stand and walk a little with aid. He complained that he did not want to ride in an automobile because "something hurts me," and he complained of pain in the back on being moved. He was told to have continued to improve but when first seen in June 1933 he was unable to stand or walk alone. He no longer cried and seemed much less irritable. In a note Dr. Carpenter stated that he had noted a weakness of the left leg which had first appeared a short time after the onset of the illness in October.

Examination on June 8 1933 revealed a very thin, pale child. He seemed quieter than a normal child of his age. Except for the malnutrition the chest and abdomen seemed entirely normal. Neurological examination revealed no abnormalities of the cranial nerves, the upper extremities seemed quite normal but the left leg showed slight generalized wasting, particularly in the gastrocnemius and gluteal muscles. The left foot was everted. There was also definite weakness of the left lower extremity. The tendon reflexes of the upper extremities were diminished but equal. In the

lower extremities the knee jerk was less active on the left than the right and the left Achilles tendon reflex was absent whereas it was present on the right. The abdominal reflexes were present and equal on the two sides. Babinski's sign was not present. No sensory disturbance could be found.

At that time the child weighed 9 kilograms (19.8 pounds). Laboratory examination revealed a normal urine, a blood count of 5,000,000 erythrocytes, 8,000 leucocytes, and 78 per cent hemoglobin. The Wassermann and Kahn tests on the blood were negative, as was the test with tuberculin of 1:1000 dilution. Roentgenological examination was made of both lower extremities, the pelvis, the lower lumbar spine and sacrum, and the stomach. All were reported as normal.

It was felt that his condition was the result of an acute anterior poliomyelitis. The parents were given instructions as to diet and physiotherapy and the patient was discharged.

On January 15 1934 the mother wrote that the child had improved slightly, had a better appetite, and had gained a few pounds. However in December 1933 he had

Fig. 1. Lateral roentgenogram of the lower thoracic and lumbar spine. The lipiodol arrested at the upper border of the eleventh thoracic vertebra is seen above. The anteroposterior diameter of the spinal canal is greatly increased at the level of the first, second and third lumbar vertebrae as compared with the normal canal at the fourth and fifth lumbar vertebrae. The pedicles of the first lumbar vertebra are decalcified.

Fig. 2. Anteroposterior view of the spine. The lipiodol resting upon the superior curved surface of the tumor is present above. The canal from the twelfth thoracic to the third lumbar inclusive is grossly widened in fact it is wider than the bodies of the vertebrae at this level. The pedicles of the twelfth thoracic, first, second and third lumbar vertebrae particularly the middle two are markedly flattened as compared with the normal pedicles of the fourth and fifth lumbar vertebrae.

Mural nodule

Fig. 3. Drawing of tumor made at the operation. The spinal canal is grossly dilated. The cyst has been drawn to one side and rotated so as to reveal the flattened spinal cord beneath it and the mural nodule in its lower part which was attached to the spinal cord.

Attachment of mural nodule to spinal cord

Fig. 4. Drawing of spinal canal after removal of tumor showing the dilatation of the canal and the severe compression of the spinal cord and its roots. The defect in the posterior columns from which the mural nodule was removed is shown.

begin to complain of "severe pains in the left leg, particularly in the region of the ankle. These pains occurred repeatedly both day and night and were aggravated by using the leg. It had also been noted that lately there had been periods of infrequent urination. This was the first evidence of any involvement of bowel or bladder.

Re-examination. Because of this new development the child was seen in the out-patient department on January 30, 1934. His weight was 10.3 kilograms (22 pounds, ounces). The lungs, heart, and abdomen seemed perfectly normal. The left leg seemed stronger than it had been. The knee jerks were both absent as was the ankle jerk on the left. No sensory loss could be detected. During the examination the patient suddenly cried out with severe pain in the left ankle. This persisted for about 10 minutes. During this time mobility of the leg remained unchanged. Subsequently the left lower extremity was "cold and clammy" while the right remained warm and dry. The mother stated that she had repeatedly observed the same change following similar attacks of pain.

Röntgenograms were made of the hips and pelvis but these were reported as normal.

The child was again returned to his home. On February 19, 1934, Dr. Carpenter wrote that the child seemed more emaciated than ever and was suffering greatly from the attacks of pain.

Road mission. On March 19, the child was readmitted to the clinics. The parents stated that the pains had gradually grown more severe until February 20, when the child had suffered a particularly bad attack. Following that a rash had appeared on the leg which according to the family

physician followed "the nerve. The rash soon disappeared and subsequently he was practically free from pain, but developed a swelling on the external margin of the left foot.

His weight at this time was 9.6 kilograms (21 pounds, ounces). The general physical examination except for the emaciation was negative. Neurological examination revealed weakness of both lower extremities, especially the left, absence of all tendon reflexes in the legs, wasting of the entire left lower extremity, rigidity of the lower back, and no sensory disturbance.

On March 26 a lumbar puncture was performed. The spinal fluid was deep amber in color and coagulated on standing.

Röntgenograms were made of the vertebral column from the seventh cervical vertebra to the coccyx and were reported as normal.

On April 4, under ether anesthesia, the distena magna was punctured and cubic centimeter of lipiodol injected. Subsequent roentgenograms revealed that the lipiodol had descended the spinal canal to the level of the eleventh thoracic vertebra where it was completely arrested by a dome shaped mass (Figs. 1 and 2). With this additional information a review of this and previous roentgenograms revealed a gross dilatation of the spinal canal from the twelfth thoracic to the third lumbar vertebra inclusive, in both the lateral and anteroposterior diameters. There was visible a distinct flattening of the medial surfaces of the pedicles of these vertebrae with definite narrowing of their transverse diameters. In the lateral view, it was obvious that the pedicles, particularly those of the first lumbar vertebra were markedly declassified.

Fig. 5. Epithelial lining of the thin cyst wall. It is composed of a single layer of cuboidal epithelium. Hematoxylin and eosin. $\times 1310$.

The child was again examined on April 9, at which time the upper extremities were normal. There was marked rigidity of the neck and entire back. The spinous processes of the ninth thoracic vertebra seemed unduly prominent but because of the severe emaciation all of the spines were very distinct. There was definite tenderness of the lower thoracic and lumbar regions posteriorly. The abdomen was somewhat distended but no localized weakness could be detected. All abdominal reflexes were active. The cremasteric reflex was present on the right but absent on the left. There was definite atrophy and weakness of both lower extremities. All movements were possible but weak. The patient was unable to stand even when grasping the sides of his bed but could sit up unaided. The right knee jerk was fairly active but the left was absent. Both ankle jerks were present and ankle clonus was elicitable on the right. Babinski's sign was positive bilaterally. There was definite flaccidity especially of the left lower extremity. No sensory loss to pin prick, cotton, vibration or sense of position could be detected. Marked persistent erection of the penis was present throughout the examination and was repeatedly observed thereafter.

It seemed definite from this examination that the lesion of the nervous system which was previously manifest by weakness, atrophy and loss of tendon reflexes had now extended to a higher level in the spinal cord as shown by the hyperactive reflexes, clonus, and the presence of Babinski's sign.

Diagnosis. With the aid of the lumbar puncture and X-ray findings a diagnosis of a large tumor of the lower spinal cord and cauda equina was made.

Operation. April 10, 1933. Under ether anesthesia the spaces and laminae of the eleventh and twelfth thoracic and upper four lumbar vertebrae were exposed and resected. The laminae of the twelfth thoracic and upper three lumbar vertebrae were extremely thin and had been pushed far posteriorly greatly reducing the length of the spinous processes. The spinal canal was dilated to two or three times the normal size (Figs. 3 and 4). The dura mater was thin and translucent. Within it was found a large thin walled cyst which lay beneath the arachnoid (Fig. 3). This cyst extended from the eleventh thoracic to the upper border of the fourth lumbar vertebra. It was filled with a very thick tenacious, glary opalescent material which jelled when exposed to the air. The cyst was slowly dissected from the spinal roots which lay on either side and the spinal cord which was beneath, i.e. anterior to it. It was impossible to remove the cyst intact so the contents were evacuated (35 cubic centimeters, 38 grams) and the entire cyst removed. In the lower part at the level of the third lumbar vertebra, there was an elongated bean-shaped solid nodule measuring about 1.5 centimeters by 0.5 centimeter in the anterior wall. This was the only point at which the tumor was

Fig. 6. Section through the entire thickness of the teratomatous mural nodule. A. Stratified cuboidal columnar epithelium lining the cystic cavity. B. mucous glands. C. adipose tissue. D. hyaline cartilage. E. posterior columns of the spinal cord. Hematoxylin and eosin. $\times 15$.

attached to the surrounding structures. Here entered all of its vascular supply. This nodule was firmly attached to the posterior surface of the spinal cord about 1.5 centimeters above the tip of the conus medullaris. It was carefully removed from the spinal cord by blunt dissection.

After the tumor was removed (Fig. 4) one could see the roots of the cauda equina lying against the wall of the dilated spinal canal and the spinal cord which had been flattened to a thin ribbon lying on the anterior wall of the canal. The tip of the conus medullaris extended almost to the lower border of the fourth lumbar vertebra. In the midline of the posterior surface of the lower end of the spinal cord was a defect from which the tumor had been dissected. The wound was closed without drainage.

Postoperative course. Following the operation the patient was incontinent but his recovery was otherwise uneventful. He was discharged on April 24, 1934, 14 days after operation. At that time examination revealed good strength in all muscles of the lower extremities except for those concerned with movement of the left foot, in which strength was only fair. Reflexes were normal except for increased ankle jerks with ankle clonus bilaterally and a positive Babinski's sign on the right. There was no sensory loss. The child was able to stand when grasping the sides of his crib-bed. Two weeks later on May 8 the child was seen in the out patient department. The change in his condition was striking. His parents stated that whereas before they had had great trouble getting the child to eat, each meal requiring about 2 hours, he now ate readily and demanded more as well as having to be fed between meals. He no longer suffered from any pain. He slept very well. The child's face was fuller, and his color good in contrast to his pale, pinched expression before operation. He was able to

Fig. 7 Stratified ciliated columnar epithelium which covered the inner surface of the mural nodule. There are many large goblet cells. Hematoxylin and eosin $\times 800$.

Fig. 8 Mucous glands from the mural nodule. Hematoxylin and eosin $\times 302$.

stand without aid and to walk with very little assistance. There was no longer any trouble with either bowel or bladder. When last seen on June 5, 1934, the patient was able to walk quite well without any assistance.

*Microscopical examination.*¹ The wall of the cyst and the mural nodule were fixed in formalin, sectioned serially stained with hematoxylin and eosin and impregnated by Freeman's silver technique for nerve fibers and Perls's method for reticulum.

The cyst wall consisted of two parts, a loose vascular connective tissue which covered its surface and a lining epithelium. In many places this epithelium was composed of a single layer of low cuboidal epithelium (Fig. 5). Elsewhere it was two to three cells in thickness. Upon the inner surface of these cells were many cilia.

The mural nodule was much more complex (Fig. 6). It consisted of two portions between which there was no sharp line of cleavage. That portion of the nodule nearest the cyst cavity was composed of teratomatous tissue. On its surface was a thick layer of ciliated stratified columnar epithelium in which many goblet cells could be seen (Fig. 7). Lying beneath this epithelium was a loose connective tissue in which were embedded many pieces of hyaline cartilage. Lying in close relation to the cartilage in a manner strongly suggestive of the trachea, were found nests of glands (Fig. 8). It was the opinion of Dr. R. R. Bensley of the Department of Anatomy that these glands were mucous in type and most closely related to those normally found in the posterior part of the palate, although they bore some

resemblance to those of the trachea. These glands were connected by several ducts to the interior of the cystic cavity into which they presumably poured their secretion. In this same area were found bundles of myelinated nerve fibers (Fig. 9). Through the serial sections these could be traced to their origin from a small group of large multipolar ganglion cells at one end of the mural nodule (Fig. 10). There were also areas of adipose tissue (Figs. 6 and 9) and several isolated collections of lymphocytes. Tissue which could be definitely identified as muscle could be seen.

That portion of the nodule farthest from the cystic cavity and in close contact with the spinal cord consisted primarily of a great number of longitudinally arranged, parallel nerve fibers which were best shown by Freeman's technique of silver impregnation for nerve fibers (Fig. 11). In places these fibers were closely crowded together; in others they were more sparse. Not all of them were normal, many being swollen and fragmented, while others possessed degenerative end-bulbs and end-loops. In places where the nerve fibers were few there was a proliferation of glial tissue. It was felt that most probably this area was a portion of the posterior columns of the spinal cord which was intimately connected with the teratoma and had been removed with it. This was regarded as particularly likely because of our inability to demonstrate any neurocytes from which these nerve fibers might have arisen. Those few ganglion cells which had been found were definitely related to the bundles of myelinated nerve fibers found in the more superficial parts of the tumor. At no point was there any evidence of any connection or relationship of the tumor or the cyst to the ependyma-lined central canal of the spinal cord.

Portions of the gelatinous contents of the cyst were fixed in various fixatives, embedded, and stained with hematoxylin and eosin. Microscopical examination revealed no definite cells. There were a number of large indistinct eosinophilic cytoloid bodies. These were entirely devoid of nuclei. The gelatinous material itself presented a uniformly finely granular eosinophilic appearance.

NATURE AND GENESIS OF THE TUMOR

This tumor undoubtedly comes under the classification of teratoid or bilaminar tumors. As Hoen

¹ We are deeply indebted to Dr. George Bartschman of our Department of Anatomy who very kindly assisted us in the microscopical examination of this tumor.

Fig. 9. Section from the mural nodule showing bundles of unmyelinated nerve fibers, *C* in the neighborhood of the, *A* hyaline cartilage *B* mucous glands and *D* adipose tissue. Freeman's method for nerve fibers. $\times 215$.

pointed out, this is true for all examples of intradural teratoma. And as has been true in all other instances the germinal layer not represented in the various structures which compose this tumor is the entoderm. All the structures present would be classified as arising either from ectoderm (ciliated stratified columnar epithelium ciliated cuboidal epithelium mucous glands, ganglion cells unmyelinated nerves) or mesoderm (cartilage adipose tissue, connective tissue). Such teratomatous neoplasms as this are probably not to be explained by a simple mechanical embryological malformation such as gives rise to dermoid and epidermoid cysts, or the congenital dermal sinuses recently reported by Walker and Bucy. In these, simple inclusion of a portion of the surface ectoderm in the underlying mesodermal tissues gives rise to a neoplasm or malformation composed solely of proliferated epidermis and dermal structures. This complex teratomatous neoplasm composed of elements largely devoid of any embryological relationship to the nervous system or its anlagen probably arose from a maldevelopment of the ovum the misplacement of some multipotential germinal cells early in embryonic development, forming as Bucy and Haymond have pointed out for another similar tumor a twin which had not gone on to full development. It would seem that the explanation most favored by Kubie and Fulton that these cysts probably represent ependymal diverticula of the central canal of the spinal cord is an entirely inadequate explanation because of the lack of demonstrable relationship between the ependyma and such structures as cartilage fat tissue, and mucous glands.

DISCUSSION OF THE CLINICAL ASPECTS

This case again demonstrates the value of lumbar puncture in cases of obscure diseases of the spinal cord. It is also illustrative of the point that the diagnosis of anterior poliomyelitis is particularly to be questioned when the manifestations are somewhat unusual or the disease is progressive. In the present case suspicion that the diagnosis which had been made was incorrect was first raised with the appearance of subjective pain. The pain can in all probability be attributed to irritation of the posterior lumbar nerve roots although the possibility that it was secondary to intense vascular spasm must be considered especially so as the attacks of pain were followed by a localized vasoconstriction which was manifested by the left lower extremity becoming cold and clammy. These attacks may have been due to irritation of the vasoconstrictor nerve fibers arising from the spinal cord. However it is generally conceded that the efferent nerves to the sympathetics arise only from the thoracic spinal cord whereas the tumor in this case was limited largely, if not entirely to the lumbosacral portion of the cord. It is true that Oughterson Harvey, and Richter have presented evidence of some vasoconstrictor fibers arising from the lumbosacral cord but it is questionable if irritation of these few fibers alone would have given rise to such severe vascular spasms. The attacks of course may have been elicited in some obscure reflex manner. The relationship of the pain and the vasoconstriction to the rash which subsequently developed is also not clear. This rash was presumably of the nature of a herpes zoster. And although the pathogenesis of

Fig. 10. Ganglion cells found at one end of the teratoma. The myelinated nerve fibers which pass throughout the tumor can be seen arising from the ganglion cells. At this point the ganglion cells and nerve fibers are embedded in adipose tissue. Freeman's method $\times 150$.

it be undetermined it is of interest to know that intraspinal neoplasms can produce such a condition.

With the appearance of these phenomena obviously not explicable on the basis of an anterior poliomyelitis, the progression of the paralysis and the development of hyperactive reflexes, clonus, and positive Babinski's sign, it was evident that the previous diagnosis was incorrect.

The lumbar puncture which revealed the typical findings of a complete obstruction of the spinal subarachnoidal space confirmed this belief.

The roentgenograms (Figs. 1 and 2) of the lumbar spine were typical of an enormous expand-

ing intraspinal lesion. Similar pictures have been observed in other cases in the cervical as well as the lumbar region. One such case with a very large ependymoma filling the entire lumbar canal dilating it and eroding the pedicles and laminae has been recently reported from this clinic by Hamby.

Lipiodol was utilized in this case because with the absence of any sensory change the confusing nature of the motor alteration, both flaccid and spastic phenomena being present, it was impossible from the neurological examination accurately to determine the upper limit of the tumor. As is so often true with tumors in this region (Harkins) the illustrations show that the lipiodol successfully defined the upper limit of the neoplasm. In this clinic no irritation of more than very temporary duration and slight intensity has ever been observed from lipiodol introduced into the subarachnoidal space, and there would seem no reason for hesitation in its employment whenever it is indicated.

It has been apparent in many cases that severe compression of the spinal cord may be compatible with retention of normal or nearly normal sensation. This seems especially true in children and has been noted by Walker and Bucy in cases of subdural abscess of the spinal cord in which there was marked alteration in the motor functions of the spinal cord with but little effect upon sensation. Why this should be so is not apparent. It is true that in the present instance the paralysis was probably in a large measure the result of compression of the anterior horn cells rather than the pyramidal tract. However that is a situation

Fig. 11. Posterior columns of spinal cord removed with mural nodule. This area is composed of a large number of nerve fibers all running in the same area, parallel to the spinal cord. Many fibers are degenerated and close inspection will reveal swollen fibers and a few degenerative end-balls even at this low magnification. Freeman's method $\times 70$.

TABLE I—REPORTED CASES OF TERATOID TUMORS OF THE SPINAL CORD

Author	Sex, age in years	Location	Size	Ectodermal structures	Mesodermal structures	Structures hard to classify
1. Gowers, 1876	Adult	Conus medullaris	5 x 5 0.4 in		Connective tissue, striated muscle, fat	
Gerlach, 1891	M 36	Upper cervical	about 5 mm long		Connective tissue primitive and adult muscle fibers, cartilage	Embryonal tissue
2. Forbes, 1905	M 55	Midcervical	Size of hamot bone		Cellular connective tissue, embryonal and adult striated muscles, fat cells, multinucleated giant cells (osteoclasts?)	
4. Frick, 1911	F 4	Second to fifth lumbar vertebrae		Numerous blood hairs	Connective tissue, bone with myeloid tissue in marrow fat	
5. Andre-Thomas and Querry, 1913		Cervical and dorsal cord		Ependymal cells, glial elements (glioma)	Connective tissue, striated muscle, numerous blood vessels	
6. Belschowsky and Unger, 1920	M 37	Third cervical	Twice walnut size	Fine hairs	Connective tissue, fat cells, endothelioma or alveolar sarcoma	
7. Hammond, 1926	F 21 days	Sacral	6 cm diameter	Stratified squamous epithelium, nerve, glial cells, ependyma, ependymal glioma (?)	M, mucous connective tissue, smooth muscle, cartilage, fat, lymphoid cells	Cysts lined with high columnar cells

peculiar to the present case whereas the fact that the sensory pathways are more resistant to pressure than the motor is borne out by cases of tumors in all parts of the spinal cord. In fact this observation concerning the greater resistance of the sensory pathways is not limited to such agents as mechanical pressure but is also seen in other conditions. For instance in both multiple sclerosis and progressive muscular atrophy sensory changes are uncommon and of little moment whereas microscopic examination of the spinal cords from such cases often reveals marked demyelination which is not limited to the efferent or motor tracts but is disseminated throughout the spinal cord.

One is also often amazed at the amount of recovery which occurs after such a severe degree of spinal cord compression. This seems especially true of children and was observed in the cases of subdural abscess as well as in the present case, in all of which the compression was of long standing. Not only is the degree of recovery striking but its rapidity as well. In the present instance the patient after months of illness malnutrition and in-

capacity was able to stand 2 weeks after operation and to walk in 4 weeks.

LITERATURE

The reports dealing with intradural teratomata were thoroughly dealt with by Hosoi in 1931. There do not appear to have been any further additions to the literature since that time. It does not seem necessary to repeat Hosoi's review, rather I have appended his table (Table I) to which I have added the present case.

In 1932 Bucy and Hammond recorded an example of a teratoma arising outside of the spinal canal but connected with its neural contents by a narrow stalk. They found two similar cases those of Sonntag and Aloï in the literature. These extra spinal teratomata, all intimately connected with the nervous system, are in all probability closely related to those arising within the dura. They are very similar in gross and microscopical appearance.

SUMMARY

A case of bilateral teratomatous tumor arising from the posterior columns of the lower end of the

spinal cord is here recorded. The tumor lay within the arachnoid and was obviously of long standing for it had produced a marked dilatation and erosion of the spinal canal. The growth had severely compressed the spinal cord, this compression in turn giving rise to a mixed and alternating spastic and flaccid paraplegia with considerable subjective pain but without detectable sensory disturbance. A laminectomy was made and the entire cystic neoplasm was removed. This operation was rapidly followed by a striking recovery of all functions.

SYMPATHETIC OPHTHALMIA

IN the group of inflammatory diseases of the uveal tract which come under the general classification of uveitis sympathetic ophthalmia stands out as a clinical entity. It follows penetrating injuries to the eye, operations on the eye involving the iris or ciliary body, and rarely non penetrating injuries such as contusion and intra-ocular growths. The incidence is comparatively rare yet the insidiousness of the disease and the great probability of total loss of vision when it occurs make it the most dreaded of complications in cases of injury to the eye. Early diagnosis, prophylaxis and treatment are of great importance from the standpoint of in dustrial compensation.

The onset of symptoms has been noted 2 days after the injury the average period however, has been from 2 weeks to 6 weeks, the longest period reported has been 48 years. The symptoms of sympathetic ophthalmia are not always easily recognizable in the early stages particularly in cases in which the onset is delayed or in which there is obscure or uncertain evidence of initial injury but by bio-

microscopic examination of the aqueous humor in the post lental space and about the inferior angle of the anterior chamber, the presence of cells may be detected before other signs of the disease appear. Low intra-ocular tension mild circumcorneal injection, cells appearing in the aqueous humor of a previously healthy eye a few days or weeks following a penetrating injury to the other eye, constitute sufficient grounds for presumptive diagnosis of sympathetic ophthalmia and warrant energetic therapeutic measures.

The answer to the question of what therapeutic measures are adequate to arrest the disease is not to be found in any textbook or treatise. As is usually the case when an adequate method of treatment is not known many methods are recommended. A basis for specific treatment depends on etiology. There are many theoretic and some demonstrable explanations for development of sympathetic ophthalmia, none of which is conclusive, but the most highly regarded theories at present are as follows: (a) infection from without by a bacterial agent that has or that acquires, affinity for uveal tissue by penetration into the injured eye whereupon it becomes particularly potent and affects the fellow eye by transmission through the blood or lymph or by migration along the optic nerves, (b) the presence of a filtrable virus somewhat similar in action to the virus of herpes, (c) allergy particularly to uveal pigment, and (d) endogenous tuberculosis. There are some reasons for believing that the etiological factors may be different in different cases but the histopathological picture is characteristic and does not support this assumption. It is ex-

tremely difficult to reproduce the disease experimentally. Although a great deal of information has been gained from laboratory studies of the disease, treatment must yet be based on clinical experience.

During the decade of the World War there was developed a great confidence in the efficacy of parenteral injection of foreign proteins as a prophylactic against and for treatment of ocular inflammation following injury. The value of antitetanic serum after injury was generally acknowledged, but it was regarded as a specific agent. The low incidence of sympathetic ophthalmia from injuries to the eyes of soldiers in the war has been attributed to the use of antitetanic serum and prophylactic vaccines. Fear of anaphylaxis restricted its applicability in some cases. There were, however, no dangerous complications following parenteral injection of sterilized milk or properly prepared typhoid vaccine. Diphtheria antitoxin was regarded as particularly dependable and safe for children, and as sympathetic ophthalmia occurs most often in children, the remedy became very popular.

When used as a prophylactic, foreign proteins are so effective in preventing the disease that sympathetic ophthalmia now is regarded as one of the most unlikely complications of surgery of the globe or following injury to the eye, even when the operation or the injury is in the so-called danger zone. By energetic treatment of the disease in the early stages by the same means, it often can be arrested and vision saved. This clinical experience points out two obvious and significant truths: (1) that effective therapeutic measures may be developed on the basis of clinical experience without regard to the results of laboratory investigation of etiological factors and without a full understanding of the ways in which healing is brought about; and (2) that clinical experience in the use of foreign protein for

prophylaxis and treatment of sympathetic ophthalmia has shown it to be so effective when properly given that it should be adopted as a routine procedure in every case of injury that makes the eye subject to the disease.

W. L. BENEDICT

PNEUMONECTOMY AND LOBECTOMY

UNTIL 4 years ago no patient had ever survived the removal of an entire lung, and until 6 years ago the danger of the complete removal of a pulmonary lobe was so great as to be prohibitive. The phenomenally rapid technical advances that have been made in the operations of pneumonectomy and lobectomy during the last few years furnish another illustration of the successful application of physiological principles to surgical problems.

During the last 4 years at least six total pneumonectomies have been successfully performed for bronchiectasis involving an entire lung, and at least twelve pneumonectomies for malignant disease. Although the present mortality rate of approximately 25 per cent will probably be considerably reduced by the application of the lessons already learned, pneumonectomy will always be a relatively dangerous operation. A simple wide exploratory thoracotomy undertaken to determine the operability of a carcinoma in an old person whose general resistance is poor is, however, apt to prove to be a more hazardous operation than the actual removal of a lung in a young or middle-aged person in good condition.

The fact that pneumonectomy has been demonstrated to be possible, and not particularly hazardous in patients in reasonably good condition, has already stimulated interest among internists and bronchoscopists in the diagnosis of bronchial carcinoma in the operable stage. As a direct result of this

growing interest in early diagnosis, it is almost certain that a steadily increasing number of successful pneumonectomies, followed by indefinitely prolonged freedom from recurrence of carcinoma, will be reported.

The surgical problems presented by carcinomatous and bronchiectatic patients are quite different. Bronchial carcinoma is frequently located so centrally that the stem bronchus must be divided in its intramediastinal portion after the separate ligation of the pulmonary artery and veins. The dissection within the mediastinum and the healing of the sutured bronchial stump are favored by the one stage operation that is usually possible in cases of carcinoma. A one stage operation is feasible because the absence of pronounced pulmonary suppuration in the operable phase of carcinoma reduces the danger of infection of the pleural cavity, and the absence of extensive pleural adhesions reduces the operating time. The pleural cavity may be tightly closed without tube drainage thus permitting the postoperative pleural exudate to become rapidly organized and pull the ribs, hemi diaphragm, mediastinum, and remaining lung toward the pleural cavity until it is obliterated. In this event a thoracoplasty is of course unnecessary.

All the successful pneumonectomies for carcinoma have been one stage operations and for bronchiectasis two stage. A one stage operation in a bronchiectatic patient would be unduly hazardous because virulent infection would probably attack the pleura that has not been protected by the traumatic inflammatory wall that a preliminary stage would have produced. Open drainage of the empyema, or the early opening of the infected hilar bronchus, after a one stage operation would expose the patient to grave danger of cardiorespiratory decompensation from pendulum respiratory movements of a mediasti-

num that was as yet mobile. Since the stem bronchus need not be divided within the mediastinum in bronchiectatic patients, the extramediastinal portion of the hilum or preferably the individual lobar hila may at the second stage be circumferentially ligated or sutured after their division. Because of the extensive pleural adhesions that are usually present in patients having bronchiectasis of an entire lung a posterior incision is best, whereas an anterior incision is preferable for carcinoma patients because it gives direct access for the dissection of the pulmonary artery and veins in the anterior part of the hilum and because pleural adhesions are usually only few in number.

The mortality rate from the newly developed lobectomy operations for unilateral bronchiectasis (in bilateral disease the rate is prohibitively high) has been reduced to less than 13 per cent in a total of 116 patients operated on in the four clinics in which the death rate is the lowest. Fifty nine of these patients were operated on by the two stage technique with a mortality rate of 10.2 per cent and the remaining 57 by the one stage technique with a mortality rate of 12.5 per cent. The published mortality rates in other clinics using the one stage operation are 11.1 per cent, 23 per cent, 25 per cent, and 29.6 per cent, respectively. In spite of the lower death rate of the two stage operation, there is at present a sharp division of opinion as to which operation is the better.

In the two stage lobectomy the undiseased lobe is adherent at the time that the second stage is performed, and the mediastinal, diaphragmatic, and costal pleura over the lobe that is to be removed contains a traumatic inflammatory barrier against the infection that will follow the removal of the lobe. These two factors protect the patient against the development of a virulent total empyema and

against the pendulum respiratory movements of the mediastinum and the paradoxical movements of the ipsilateral lobe that would probably occur if the hilar bronchus opened prematurely or if the thoracic wall incision could not be kept tightly closed during the first week or two after operation. The chief disadvantages of the two stage operation are that the patient must be operated on twice and that the empyema that occupies the space that contained the diseased lobe is larger and takes longer to become closed than does the empyema remaining after the one stage operation for the reason that the adhesion of the remaining lobe to the thoracic wall prevents its expanding rapidly to fill the empyema cavity. A further disadvantage of the two stage technique is that approximately half of the patients require a muscle graft operation to close a residual bronchial fistula.

The one stage operation is convenient for the patient and surgeon and by virtue of the rapid filling of the space from which the diseased lobe was removed the postoperative convalescence is relatively short the broncho-pleural fistula that develops usually closes

spontaneously. The chief disadvantages of the one stage operation are (1) the relatively long operating time required increases the danger of shock and postoperative pneumonia, (2) the tourniquet that is used to control the hilar vessels while the hilum is being closed by suture may slip with a resulting fatal hemorrhage (3) some of the many divided hilar vessels cannot be identified for certain closure by the hilar sutures, and may be the cause of a fatal postoperative hemorrhage (in the two stage operation the hilum is usually tightly ligated *en masse* and operative or postoperative hemorrhage is a rare complication) (4) severe infection of part or all of the pleural cavity sometimes occurs. In spite of certain obvious advantages of a one stage lobectomy the two stage procedure seems at the present time to be the safer and therefore, the preferable operation.

The progress that has already been made with the operations of pneumonectomy and lobectomy justifies the inclusion of pulmonary carcinoma and intractable cases of unilateral bronchiectasis among the curable diseases.

JOHN ALEXANDER

EARLY AMERICAN MEDICAL SCHOOLS

THE MEDICAL FACULTY OF LAVAL UNIVERSITY, QUEBEC

PROFESSOR A. VALLÉE, M.D. F.R.C.P.C. QUEBEC, CANADA

THE Medical Faculty of Laval University has been teaching for some 80 years since it was organized in the fall of 1853. To understand its real origin, one must go back as far as the beginning of the French colony of Nouvelle France and follow up the evolution of French teaching which has been followed since the foundation of the school.

In 1663 the first Bishop in North America François de Montmorency Laval, established the Quebec Seminary. In 1676, a Royal Charter was received from the French King Louis the XIV. The Seminary created Laval University in 1852 and obtained then a Royal Charter from Queen Victoria of England together with the Papal Bullas as a Catholic university. From this moment Laval jealously preserved that classical education of the French and other great universities in Europe such as Oxford, Cambridge, Rome and Louvain. Laval has four faculties: divinity, law, medicine, and arts comprising sciences and letters. French is the teaching language, and technique books in the medical faculty are all in French.

These notions were necessary to have in full sight the situation of the Medical Faculty of Laval University.

Before its foundation the student who desired to enter medical practice in Quebec City had to study with a practitioner who could initiate the future physician to the first notions of medical science and the practice of medicine and surgery. Since 1847 a medical school had been organized which was called L'École de Médecine incorporée de la Cité de Québec. In this school medicine and surgery were taught and clinical lectures were given at the Miséricorde Hospital, while dissecting rooms were provided successively in different parts of the city. The professors of this school were called upon to become the first professors of the Medical Faculty of Laval. At the opening of the university in 1854 the faculty had 6 professors with Dr. Jean Blanchet as dean. It counts actually 20 professors, 5 are full time, 19 associate professors, 6 in charge of lectures and 27 assistants. Of this staff of 66, 51 have had postgraduate work in Paris, Strasbourg, Bordeaux, Lyons, for periods varying from 1 to 3 years; others have done postgraduate work in New York or other American cities.

To be admitted to the medical faculty the student must either be a bachelor of arts of Laval or any recognized university, or have passed the special

examination of admission to the study of medicine in the Province of Quebec established by the Medical Board of the Province, or submit the regulations of admission wanted in the Province or country to which he belongs. For American students, they must prove to have had 3 years of premedical work for entrance in the first year and have been studying in a medical faculty classified A for other years. The students numbered 263 in 1933-1934.

The course in medicine is a full 5 year medical course of 8 months. All lectures are given in French. Semestral examinations take place at the end of January and the beginning of May. Final examinations start on the fifteenth of May in every year. The presence of every student to lectures, practical work, and clinics is controlled every day. Lectures and practical work take place in the building of the medical faculty which was rebuilt in 1922. Clinics are given in the different hospitals connected with the faculty which include: The Hôtel Dieu de Québec, St. Sacrement Hospital, Laval Hospital, Maternity Hospital, Infant's Hospital (Crèche St. Vincent de Paul), Neuropsychiatric Clinic (Clinique Roy Rousseau) and Insane Asylum (Hôpital St. Michel Archange). Nominations in these hospitals are all controlled by Laval University; the total beds numbering over 4,000 of which 2,000 belong to the Insane Asylum.

Technical books on every subject are indicated to the students and must be bought at the university at the beginning of each year without the possibility of handing them over. The rest of the material, comprising microscopes and experimental apparatus, microscopic and macroscopic collections of specimens is furnished without charge in all departments.

A library of 5,000 books, with 145 periodicals, is at the disposal of the students at the medical faculty in addition to the possible use of the university library which contains over 150,000 volumes. The library is opened daily from 9:00 a.m. to 6:00 p.m. and from 8:00 to 10:00 in the evening. Special indexes are at the disposal of the workers.

Special lectures are given every year by noted medical men and students are admitted to all meetings of the medical societies at the school or in the hospitals.

MEDICAL SCHOOL

In 1922 owing to the activities of a group of professors and the elaborate direction given by the new

dean, Professor A. Roussseau, the school has been totally rebuilt and all departments organized to look after the practical training of an average of 50 to 60 students per year.

On the top floor stands the department of biology, histology and embryology under the direction of Professor Potvin, with large practical work laboratory for the first year students with a possibility of accommodation for over 80 students, private laboratory for the professors and helpers.

Next is the department of anatomy directed by Professor Garneau. The large dissecting room as well as the annexed lecture room can be attended by 100 workers. Complete collections of bones, normal anatomy specimens, charts and moldings are at the disposal of the students and large working shops are fitted to prepare all the material at the school. Private laboratory for the professor and for the prosectors with all necessary outfits completes the material organization for anatomy teaching.

The next floor is entirely occupied by the services of physiology and biological chemistry comprising laboratories for practical work in physiology at which students are trained by groups, large laboratory for biological chemistry laboratories and offices for the professors and work rooms to prepare the material together with a large lecture room. The stables of the school close to the building are under the direction of this department together with the department of biology and pathology. Physiology is under the direction of Professor Blanchet and biological chemistry actually in charge of Dr Marcoux.

The second floor of the school is occupied by the department of pathology and bacteriology. The Pathological Institute directed by Professor Vallée and Berger with the assistance of Dr E. Morin, associate professor examined and made report last year on 3,228 microscopic specimens. This department looks after the Cancer Center of Laval University which is directed by the same staff together with Professor Verina as surgeon. The department is fitted with a large laboratory for practical work and 5 private laboratories for the staff. The Museum of Pathology contains over 500 microscopic specimens of very first quality. A pathological

collection of over 12,000 microscopic specimens is at the disposal of students who receive free of charge a complete series of all lessons amounting to 115 slides. Fourteen papers were published by the staff during the last year and over 50 since the foundation of the Institute in 1928. Charts, microscopic drawings, and microscopic photographs are prepared in the department.

General lecture rooms, registrar's offices, reading room, and library occupy the main floor together with the dean's office and professors' meeting room. In the basement are the vestries, recreation room, experimental hospital for animals, book room of the library and the storing department for anatomy.

UNIVERSITY HOSPITALS

Students are obliged to follow hospitals during the third, fourth, and fifth year but are admitted even during the first 2 years. They follow the different services by rotation either as *stagiaires* or as *externes* for those who have had over 75 per cent on their marks on all subjects during the first and second year or as *internes* in the fifth year for those who after externship have obtained 75 per cent on all examinations during the third or fourth years.

Owing to the large number of beds provided by the different university hospitals as mentioned, students are distributed in very small groups in each of the medical, surgical wards or in special services and maternity. They have to look after a certain number of patients of which they are in charge, under control of the assistants and house surgeons and physicians, to report cases and besides attend the didactic clinical lectures which take place in every hospital. *Stagiaires* students rotate every 3 months, *externes* every 6 months, maintaining their service during the whole summer months as do the *internes*.

Diplomas are delivered after the fifth year to all who went through with success all written, oral, and clinical examinations, in medicine, surgery, midwifery, and pediatrics for the clinical part. No student can change from one year to another if he has failed on any subject.

The dean of the Faculty of the school is actually Professor P. C. Dagneau, and the secretary is Professor A. Vallée.

CORRESPONDENCE

MISSISSIPPI VALLEY MEDICAL SOCIETY

To the Editor A new medical organization to be known as the Mississippi Valley Medical Society was formally organized at Quincy Illinois, on April 8. The sole purpose of the new society is to hold an annual meeting each fall devoted to intensive post graduate instruction and conducted by the leading clinical teachers of the United States. The programs will be eminently practical and of particular interest to the general practitioner. The first meeting will be held in Quincy during the month of October or November and will be a 3 day session. The control of the organization is in the hands of a board of directors, consisting of one director to

each 1000 physicians in the states of Illinois, Missouri, and Iowa. Membership in the society will be open to all ethical physicians in their respective states. In order to get started quickly the board of directors has elected to place the membership fee and dues for the first year at only \$3.00 and life membership at \$25.00 provided these are paid before the time of the annual meeting. Charter membership will close July 1, 1935. Members will attend the annual meeting without payment of a registration fee.

Ethical physicians interested in the new organization are urged to communicate with Harold Swanberg, M.D., secretary treasurer, 211-224 W. C. U. Bldg. Quincy Illinois.

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as a sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

The control of the organization is in the hands of a board of directors consisting of one director to

each 1000 physicians in the state of Missouri, and Iowa. Membership is open to all ethical physicians. It is expected that all members hold membership in their respective state medical societies. For this quickly, the board of directors has fixed the membership fee and dues for only \$3.00 and life membership at \$100.00. These are paid before the time of the annual meeting. Charter membership will draw \$1.00. Members will attend the annual meeting at a registration fee.

Ethical physicians interested in this organization are urged to communicate with Dr. J. M. D. Olmsted, secretary, 1001 Broadway, Quincy, Illinois.

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as a sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

ROBERT B. GREENOUGH Boston, *President*

DONALD C. BALFOUR, Rochester *President-Elect*

HOWARD C. NATZIGER, *Chairman* THOMAS F. MULLEN *Secretary Committee on Arrangements*

THE 1935 CLINICAL CONGRESS IN SAN FRANCISCO AND OAKLAND

THE twenty fifth annual Clinical Congress of the American College of Surgeons will be held in San Francisco and Oakland, October 28-November 1, 1935. Under the leadership of a strong and representative committee, the surgeons of that great medical center on the Pacific coast have organized and are planning to provide a program of surgical clinics and demonstrations in their hospitals and medical schools that will present a complete showing of their clinical activities in all departments of surgery. The Committee on Arrangements has been assured of the hearty co-operation of the clinicians at the two medical schools and twenty seven hospitals that will participate in the clinical program.

A preliminary program of clinics and demonstrations as prepared by the Committee on Arrangements is published in the following pages. It will be noted that operative clinics and demonstrations in the hospitals are scheduled for the afternoon of Monday, October 28, beginning at 2 o'clock, and for the mornings and afternoons of each of the four following days. The schedules published at this time in tentative form will be revised and amplified as the work of the program committee progresses.

Among the special features of this year's clinical program will be (1) Cancer clinics demonstrating the treatment of cancer by surgery, radium and X-ray; (2) fracture clinics demonstrating modern methods of treatment; (3) clinics in traumatic surgery demonstrating the newer methods of rehabilitation of injured patients by surgery and physiotherapy.

In addition to the ophthalmological and otolaryngological clinics and demonstrations at the hospitals and medical schools, the committee in charge of the section on surgery of the eye, ear, nose and throat is preparing programs for scientific sessions on Tuesday, Wednesday, Thursday and Friday mornings at headquarters at which

distinguished specialists in these branches of surgery will present and discuss papers on subjects of clinical interest.

The following hospitals and medical schools will participate in the clinical program:

San Francisco—Children's, Franklin, French, Letterman General, Mary's Help, Mount Zion, St. Francis, St. Joseph's, St. Luke's, St. Mary's, San Francisco Shriners, Southern Pacific, Stanford University, United States Marine, University of California, Veterans Administration, Stanford University School of Medicine, University of California Medical School.

Alameda County—Alameda County Alameda Sanatorium, Alta Bates, Berkeley General, Children's, Cowell Memorial, East Oakland, Peralta, Providence, Samuel Merritt.

The Executive Committee of the Board of Regents is preparing programs for a series of five evening sessions. At the presidential meeting in the Opera House on Monday evening, the retiring president, Dr. Robert B. Greenough, of Boston, will deliver the annual address, and the new officers will be inaugurated. Dr. Donald C. Balfour, Rochester, president; Dr. Arthur W. Allen, Boston, and Dr. John A. Gunn, Winnipeg, vice-presidents. The American College of Surgeons oration will be delivered by Dr. George Crile of Cleveland. Sessions on Tuesday, Wednesday and Thursday evenings will be held in the Auditorium of the Veterans' Building when eminent surgeons of the United States and Canada, together with visiting surgeons from foreign countries, will present papers dealing with surgical subjects of timely importance. The annual convocation of the College will be held on Friday evening in the Opera House at which the 1935 class of initiates will be received into Fellowship in the College. The fellowship address will be delivered by Dr. Robert Gordon Sprout, president of the University of California.

Among the special features of the program for this year's Clinical Congress will be (1) A symposium on cancer, under the auspices of the College Committee on the Treatment of Malignant Diseases, on Thursday afternoon following the annual meeting at which further reports by clinicians from various parts of the country will present additional statistics on the cure of cancer. Other papers on the treatment of cancer descriptive of modern methods of treatment and the organization and administration of cancer clinics will be included. (2) A conference on fractures arranged in co-operation with the College Committee on the Treatment of Fractures on Tuesday afternoon. (3) A conference under the auspices of the Board on Industrial Medicine and Traumatic Surgery on Friday afternoon. All of these sessions will be held in the Gold Ballroom of the Fairmont Hotel.

HOSPITAL CONFERENCE

The annual hospital conference will open the Congress with a session in the Gold Ballroom of the Fairmont Hotel at 10 o'clock on Monday morning. An interesting program of papers, round table conferences and practical demonstrations dealing with problems related to hospital efficiency is being prepared for sessions to be held on Monday, Tuesday, Wednesday and Thursday in the Gold Ballroom of the Fairmont Hotel, and at several of the hospitals. A greatly increased interest on the part of surgeons in both the administrative and scientific phases of hospital work has been evidenced in recent years and the program for this year's conference will be unique in providing for discussions of subjects of interest to the three major hospital groups—medical, surgical and administrative. It is planned to make this year's program of wide interest and practical character through a careful selection of subjects to be presented and discussed by surgeons and hospital executives, particular emphasis being directed toward professional standards and the vital problems related to medical economics.

HEADQUARTERS—TECHNICAL EXHIBITION

Headquarters for the Congress will be established at the Fairmont and Mark Hopkins hotels. At the former the Terrace Ballroom and Lounge, the Gold Ballroom and other large rooms on the main floor and on the terrace have been reserved for scientific sessions and conferences, registration and clinic ticket bureaus, bulletin boards, exhibits, executive offices, etc. The Peacock Court and Room of the Dons at the Mark Hopkins will be utilized for various scientific sessions.

The Technical Exhibition, including the registration and clinic ticket bureaus, will be located in the ballroom and lounge on the terrace floor of the Fairmont Hotel. In these rooms will also be found the bulletin boards on which the daily clinical program will be posted each afternoon. The leading manufacturers of surgical instruments, X-ray apparatus, operating room lights, hospital apparatus and supplies, ligatures, dressings, pharmaceuticals and publishers of medical books will be represented in this exhibition.

LOW RAILWAY FARES

Very low railway fares will be in effect for the Congress, the railroads of the United States and Canada having authorized an extension of selling dates and return limit for round trip summer tourist tickets to include the dates of the Clinical Congress with a return limit of November 30.

SAN FRANCISCO HOTELS AND THEIR RATES

In addition to the two headquarters hotels—the Fairmont and Mark Hopkins—there are a number of first-class hotels within short walking distance of headquarters providing ample hotel facilities at reasonable rates. The following hotels are recommended by the Committee.

	Minimum Rate with Bath	
	Single	Double
Bellevue, Geary and Taylor	\$3 00	\$4 00
Californian, Taylor and O'Farrell	3 00	4 50
Clift, Geary and Taylor	3 50	5 00
El Cortez, Geary near Taylor	3 00	4 50
Fairmont, Mason and California	3 50	5 00
Caylord, Jones near Geary	3 00	4 00
Mark Hopkins, Mason and California	3 50	5 00
Palace, Market and New Montgomery	3 50	5 00
Plaza, Post and Stockton	3 00	4 00
Sir Francis Drake, Powell and Sutter	3 50	5 00
Stewart, 353 Geary	3 50	4 00
St. Francis, Union Square	3 50	5 00

ADVANCE REGISTRATION

The hospitals and medical schools of San Francisco and Oakland afford accommodations for a large number of visiting surgeons, but to insure against overcrowding attendance at the Congress will be limited to a number that can be comfortably accommodated at the clinics—the limit of attendance being based upon the result of a survey of the amphitheatres, operating rooms, and laboratories of the hospitals and medical schools to determine their capacity for visitors. It is expected therefore that those surgeons who wish to attend the Congress will register in advance.

Admittance to all clinics and demonstrations will be controlled by means of special clinic tickets, which plan provides an efficient means for the

distribution of the visiting surgeons among the several clinics and insures against overcrowding as the number of tickets issued for any clinic will be limited to the capacity of the room in which that clinic will be given.

A registration fee of \$5.00 is required of each surgeon attending the annual Clinical Congress, such fees providing the funds with which to meet

the expenses of the meeting. To each surgeon registering in advance a formal receipt for the registration fee is issued which receipt is to be exchanged for a general admission card upon his registration at headquarters. This card, which is non transferable must be presented in order to secure clinic tickets and admission to the evening meetings.

- S. A. GOLDMAN. Studies on staphylococcus infections.
- F. J. MCCARTHY. End results in infections of the hand.
- B. F. ALDEN. Relation of focal infection to Wassermann fast lues.

ORTHOPEDIC SURGERY

- GEORGE J. MCCORMACK, W. COX and R. L. DREHSEL. Fracture of neck of femur: treatment without external splinting.
- L. D. PROCTOR, A. B. STEIN and D. D. CHARNACK. Fractures of os calcis: replacement of tibial shaft by fibula following osteomyelitis, treatment of burnitis.
- R. L. WADSWORTH. Clinical demonstration of Roger Anderson "Ought-O-Matic" splint and skeletal traction and countertraction methods applicable to Thomas or Hodgen splints.
- LEROY C. ARBUTT. The shoulder joint.
- JOHN B. DE C. M. SAUNDERS. The shoulder joint.
- J. F. RIVINGTON. Vitamin C deficiency in arthritis.
- KENNY HALDEMAN and JOHN B. DE C. M. SAUNDERS. Demonstrations of bone growth.
- FRANCIS BAILEY. Heat therapy.
- F. A. LOWE. Internal derangements of knee joint, clinic and motion picture demonstration: fracture of hip, mercuric, clinic and motion picture demonstration.
- J. J. LOUVERGNE. Arthrodesis of foot.
- S. L. HARRIS. Application of Hibbs-Risser plaster for scoliosis: results of treatment for scoliosis: results of tendon transplantation. Legg-Perthes disease.
- J. J. SALLI, W. O. MONTGOMERY, V. M. DILLON and W. J. COX. Industrial surgery and orthopedics.
- J. H. O'CONNOR. Reduction of complicated fractures, closed methods, demonstration of cases, indications for open reduction.
- C. A. WALLACE. End results of open reduction of fractures: treatment of compression fractures of spine: 250 cases: fractures of clavicle and patella.
- W. W. WASSERMAN. Disabilities following fractures, factors influencing period of recovery.
- LEONARD W. ELY. Arthritis of the hip.
- D. KING. Functional anatomy and pathology of the shoulder joint.
- A. L. FISHER. Treatment of flat feet.
- MERRILL C. MERRICK. Osteogenic sarcoma of spine: relation of bacteriophage to the Orr treatment of osteomyelitis.
- NELSON J. HOWARD. Traumatic lesions of bursae, tendons and muscles.
- LEON PARKEE. Familial tendencies in Paget's disease.
- D. KING. Treatment of chronic sclerosing osteomyelitis.
- F. G. LINDSEY. Compression fractures of spine: non-union of fractures.
- F. C. BOETT. Hibbs-Risser treatment of scoliosis, dislocation of carpal scaphoid: fracture of ankle, ligamentous tears of ankle: treatment of fracture of os calcis.
- W. J. COX. Internal derangement of knee joint, rupture of ligaments, treatment of fracture of femoral neck with Smith-Petersen nails.
- KENNY O. HALDEMAN. Pathology of acute osteomyelitis: pathology of chronic infections of bone.
- RALPH SOTO-HALL and KENNY O. HALDEMAN. Fracture dislocation of cervical spine: Duncan's traction apparatus.
- PAUL E. JOHNSON, B. H. HENKINS and JOHN A. KENNELLY. Disability ratings of Veterans Administration for orthopedic conditions of the extremities.
- CARLETON ALLENBACH, JR. and J. B. McNAUGHT. Treatment of spiral fractures of tibia: open and closed methods of treatment of fractures of extremities, tuberculosis of pelvis.
- D. KING, J. M. MERRICK and R. A. SCARBOROUGH. Fracture of carpal scaphoid: surgical approaches to bones and joints, Orr method of treatment of osteomyelitis.
- NELSON J. HOWARD. Fractures of the upper end of the humerus, motion picture demonstration.

- MERRILL C. MERRICK and LEON PARKEE. Unusual fractures of the spine: treatment of osteomyelitis with surgical maggots.
- C. C. MCRAE. Injuries of small bones of the hand.
- EDGAR L. GILCHRIST. Problems in treatment of fractures.

THORACIC SURGERY

- HAROLD BRUNN, A. L. BROWN, H. ROSENBLUTH and J. J. SAMMON. Symposium on surgery of the heart with particular reference to adhesive pericarditis.
- LEO ELLINGER, PHILIP H. PITCHER, W. L. ROGERS, W. G. BUTLAND, DAVID A. WOOD, W. R. CLARK and L. H. GARLAND. Various types of bronchial stenosis: mycotic infections of the lung: tumors of the lung: emphysema.
- EMILE HOLMAY. Technical improvements in partial resection thoracoplasty: resection of transverse process, resection of scapula: ligation of the pulmonary artery as a therapeutic measure in pulmonary hemorrhage: carcinoma of lung simulating inflammatory disease.
- HAROLD BRUNN, SIDNEY J. SHIPMAN, H. BROOKS STEINHAUS, A. L. BROWN, M. W. DICKMAN and A. GOLDMAN. Lung resections, emphysema: artificial pneumothorax: parenchymal avulsion, thoracoplasty.
- ALABORN WICKES and G. D. DILLON. Thoracoplasty.
- RAY KESTLER. Diaphragmatic hernia.
- SIDNEY J. SHIPMAN. Pneumothorax in poikilotherms.
- W. B. FAULKNER, JR. Bronchiectasis: treatment of chest injuries.
- A. L. BROWN. Collapse therapy in pulmonary tuberculosis.
- S. STEINMAN. Lymphoblastoma of mediastinum.
- C. A. WALLACE. Phrenectomy for pleuropneumonia adhesions.
- A. GOLDMAN. Staphylococcal infections of the lung, chemotherapy in tuberculosis.
- T. F. MULLER. Antithoracic emphysema.
- MARY E. MATTHEWS. Experimental study of the effect of various pathological conditions upon the dual blood supply of the lungs.
- EDGAR POTTS. A simple apparatus for tidal and apical irrigation and its application in treatment of emphysema.
- DAVID A. WOOD and MARY E. MATTHEWS. Exhibit of clinical and experimental observations on the dual blood supply of the lungs in various pathological states.

NEUROSURGERY

- HOWARD C. NAFFZGER. Late results in the treatment of malignant ependymomas, brain tumors: factors influencing recovery after peripheral nerve injury: cervical ribs and "the scalenus syndrome without cervical ribs."
- HOWARD W. FLEMING. Subdural hematomas: cerebri-spinal rhinorrhea, relief of intractable pain, cranial approach for orbital tumors, craniocerebral myxomas.
- EDMUND MORRISSEY. Neurologic clinic on lesions of the cauda equina, diagnosis and treatment of subdural hemorrhage: diagnosis of subdural hemorrhage.
- O. W. JONES, JR. Spinal cord tumors.
- H. A. BROWN. Low back injuries, spinal cord injuries.
- E. B. TOWNE. Treatment of acute head injuries.
- F. L. RICHKERT. Neuralgias of cranial nerves, demonstration of patient and lantern slides.
- ROBERT AIRD. Electroencephalography: clinical and experimental: intradural alcohol injections for intractable pain.
- E. B. TOWNE, F. MORRISSEY, J. W. WOLFE and D. WOOD. Surgical lesions of the spinal cord: dynamics of epilepsy.
- L. B. LAWRENCE. Spinal cord tumors, tumors of cauda equina.
- LIX HARRIS. Regeneration of peripheral nerves of hand.

GYNECOLOGY AND OBSTETRICS

- WILLIAM G. MOORE. Endometrioids fibromyomata of uterus.
- A. M. VOLLMER. Rubin's insufflation test trichomonas vaginalis.
- R. K. SMITH. Classical cesarean section, motion picture demonstration.
- FRANK LYNCH, ALICE MAXWELL and R. S. STONE. Uterine cancer follow-up X ray therapy radium therapy.
- MARGARET SCHULZE. Special ovarian tumors.
- A. H. HEALD and ALICE MAXWELL. X ray pelvimetry direct method.
- PHILIP H. ARNOT. Conduct of labor in posterior position.
- LUDWIG EMGE. Dysmenorrhea, causes and treatment sterility diagnosis and treatment.
- C. F. FLEHMANN, P. E. HOFFMAN and GERTRUDE F. JONES. Endocrinological aspects of gynecology modern methods of diagnosis blood and urine hormone tests, biopsy of endometrium, hormone therapy.
- A. V. PETTIT. Results of hyperpyrexia in treatment of acute and chronic pelvic inflammatory disease.
- LUDWIG EMGE. Radiation therapy of carcinoma of cervix methods and end-results.
- A. M. VOLLMER. Treatment of abortions.
- MARGARET SCHULZE. Multiple pregnancies, pyelitis with pregnancy hydatidiform mole and chorio-epithelioma cardiac disease with pregnancy.
- KARL L. SCHAUFF. Fibromyoma of the uterus.
- HANS VON GELDERN. Plastic operations on pelvis.
- C. L. COOLEY. Demonstration of gynecological cases.
- R. D. DUDON. Treatment of incomplete abortions.
- D. A. DALLAS. Operations in obstetrics.
- BEVERLY SIMPSON. Separated placenta.
- ADOLPH E. SCHMIDT. Uterine bleeding.

SURGERY OF THE GASTRO-INTESTINAL TRACT

- HAROLD BRUNN. Cancer of the rectum.
- F. I. HARRIS. Cecalizing (chronic) enteritis (regional ileitis) treatment of appendix stump, noninversion.
- FRED H. KRUE. The more common complications of peptic ulcer.
- E. J. BEST, F. H. KRUE, THEODORE ALTHAUSEN and RALPH RADNOWITZ. Postoperative care of intestinal conditions.
- M. F. CUNHA. Primary duodenitis end-results of ulcer cases, types of operation, causes of recurrence.
- LEON GOLDMAN and THEODORE ALTHAUSEN. Pseudo perforation of peptic ulcer.
- J. HOMER WOOLSEY and H. GLENN BELL. Carcinoma of stomach.
- M. L. MONTGOMERY and JOSEPH M. SWINDT. Acute intestinal obstruction experimental and clinical.
- H. GLENN BELL. Subacute intestinal obstruction, localized type (chronic cecalizing enteritis).
- H. GLENN BELL and LEON GOLDMAN. Congenital lesions, tumors, diverticula of small bowel.
- M. S. WOOLY, LEON GOLDMAN and H. GLENN BELL. Carcinoma of large bowel.
- DUDLEY SMITH and J. W. MORGAN. Carcinoma of rectum.
- ASA W. COLLINS. Pylorectomy and gastro-enterostomy.
- LEROY BROOKS. Diagnosis and treatment of intestinal obstruction.
- ERNEST GREENFIELD. Radical surgery for gastric and duodenal ulcers diverticulitis of colon closure of colostomy preservation of anal sphincter.
- P. K. BROWN. Peptic ulcer indications for surgical treatment.

- W. W. WARBURN. Acute perforation of peptic ulcer complications and end results in 100 cases.
- J. A. GUILFOIL. Chronic appendicitis, end results of operation.
- J. E. BOHM. Mortality rate of operations for appendicitis.
- R. A. SCARBOROUGH. Developments in surgical treatment of carcinoma of rectum, 200 cases.
- EMILE HOLMAN. Causes for failure to control symptoms and to prevent gastrojejunal ulcer in gastric surgery.
- GUNTHER W. NAGEL, F. L. REICHERT and MARY E. MATTHEW. Chronic regional enteritis, clinical experimental.
- DAVID A. WOOD. Multiple primary carcinomata of colon complicating multiple polyposis of colon.
- NELSON J. HOWARD. Amebic granuloma of large bowel.
- HAROLD BRUNN. Carcinoma of large bowel carcinoma of rectum bowel obstruction.
- GEORGE K. RHODES. Spontaneous perforation of cecum from obstruction in distal colon.
- DANIEL SOOT. Choice of operation in gastric surgery.
- EDWARD TORHAM. End-results in surgery for gastric ulcer.
- H. P. HILL, GEORGE BARNETT, J. M. MEHRKE, J. W. CLINE, JR., CARLETON MATHEWSON JR., J. B. MC NAUGHT and A. C. MCKENNEY. Lesions of the upper gastro-intestinal tract amebic infections of liver and gastro intestinal tract.
- DUDLEY SMITH. Operation for rectal fistula and hemorrhoidectomy motion picture demonstration.

SURGERY OF THE BILIARY TRACT LIVER AND PANCREAS

- ALANSON WEEKS and G. D. DELPRAT. Common duct stone hydatid disease of liver: granuloma inguinale.
- F. I. HARRIS. Acute cholecystitis.
- CARL HOAG. Reconstruction of common duct.
- H. CLARF SHEPARDSON and HANS LISSER. Pancreatic dysfunction hypoglycemia.
- H. GLENN BELL and THEODORE ALTHAUSEN. Operative mortality and pre-operative management of cholecystitis, glucose therapy. Rose-Bengal and other tests.
- FRED H. KRUE and THEODORE ALTHAUSEN. Medical and surgical jaundice cirrhosis of liver differential diagnosis from carcinoma of stomach.
- JESSE L. CARR and FREDERICK S. FOOTE. Experimental work in human jaundice.
- KARL SCHMIDT. The bile salts.
- EMILE HOLMAN. Postoperative and inflammatory stenosis of the bile passages.
- M. W. DEBENHAM and J. M. SWINDT. Liver abscess.
- STANLEY H. MENTZER. Acute cholecystitis obstructive cholecystitis.
- ROSELYN A. YOELL. Gall-bladder anomalies.
- T. F. MULLEN. Recurrence of symptoms after biliary tract surgery.

ENDOCRINOLOGY

- R. F. ESCAMILLA. Abdominal pain of endocrine origin.
- SAMUEL COHEN and F. I. HARRIS. Treatment of undescended testicle by operation and glandular extracts.
- LEO STANLEY. Endocrinology in a penal institution.

CIRCULATORY DISEASE

- M. L. MONTGOMERY. Therapeutic venous occlusion.
- C. A. NOBLE, JR. Postoperative cardiac versus circulatory collapse.

CLINICS IN ALAMEDA COUNTY HOSPITALS—WEDNESDAY

ALAMEDA COUNTY HOSPITAL

- WHITFIELD CRANE and W. EARL MITCHELL—9 Carcinoma of stomach
 FRANK H. BOWLES and THEODORE LAWSON—10 Carcinoma of cecum
 H. W. HARRING and DON D. WEAVER—11 Carcinoma of colon
 LEMUEL P. ADAMS—12 Carcinoma of breast
 SCHMIDT EVEREDORHAM—9 Extrapleural thoracoplasty intrapleural pneumolysis clinic on phrenic interruption and thoracoplasty Discussion by CHESTER BURN
 WARREN B. ALLEY—12 Neurosurgery
 W. F. HOLCOMB—9 Arthroplasty of hip
 L. B. BAIRD—10 Arthroplasty of shoulder
 E. N. EWING—9 Total hysterectomy subtotal hysterectomy discussion of obstetrical service at Alameda County Hospital
 CLARENCE A. DUFFY—1 Gynecological cancer clinic Demonstration of intrapleural alcohol injection and presentation of cases
 ALBERT M. MEANS, LLOYD KENDALL, JOHN A. DAUGHERTY, T. I. BUCKLEY and associates—9 Perineal prostatectomy suprapubic prostatectomy resectoscopic prostatectomy Operations, demonstration of cases and discussion

Dry Clinics 2-4 30

- CHARLES A. DUKES and associates Cancer clinic
 HAROLD H. HITCHCOCK, N. A. CARY and associates Traumatic and orthopedic clinic demonstration of Sweetland cast dryer Bell table, plaster models, splints, etc.
 W. H. SARGENT and C. B. BOWEN X-ray exhibit and discussion
 GEORGE MOORE Pathological exhibit and conference

BERKELEY GENERAL HOSPITAL

Dry Clinics, 9-12

- FRANK D. WALKER Cholecystitis, observations and comments on surgical treatment
 CLAUDE H. CHURCH Ectopic pregnancy recurring on same side
 WILLIAM W. CHASE Polycystic kidney nephrolithiasis prosthetic management
 J. F. CARRISON Osteochondromatosis involving all epiphyses in one extremity clavicle drawings
 W. W. RUSCH Parathyroid disease, gross specimens and microprojections
 R. G. VAN NUY X-ray demonstration and discussion

CHILDREN'S HOSPITAL

- ROY NELSON—9 Demonstration of methods of treatment of esophageal strictures due to lye
 W. W. CHASE—9 Postmortem findings in the kidneys of children, lantern slide demonstration
 CLIFFORD SWIFT—9 Clinic on undescended testes Demonstration of postoperative results, discussion of the effect of antistasis X-ray demonstration of operation

ALTA RATES HOSPITAL

- Staff—9 Operations and dry clinics

SAMUEL MERRITT HOSPITAL

- WARREN B. ALLEY—9 Reconstruction of skull defects, operation and demonstration of cases
 W. F. HOLCOMB and D. D. TOWLE—9 Orthopedic operations and demonstrations
 MARK L. EMMERT—9 Rectal surgery and presentation of cases
 FRANK H. BOWLES—9 Thyroidectomy
 W. H. SARGENT—9 X-ray demonstration and discussion of cases
 ROBERT A. GLENN—9 Pathological exhibit demonstration of frozen section techniques and specimens
 WHITFIELD CRANE—9 30 Peptic ulcer Judd pyloroplasty
 W. EARL MITCHELL—10 30 Pelvic tumor
 HENRY KOPF—10 30 Cholecystectomy
 CHARLES A. DUKES—11 Apschysis, operation, demonstration of thoracic cases Discussion by HAROLD TRIMBLE

Dry Clinic, 2-5 30

- H. N. ROWELL, A. M. SMITH, W. H. STREETMAN, A. A. ALEXANDER, W. S. KUBER, STEWART V. IRWIN, H. GORDON MACLEAN, FLETCHER B. TAYLOR, VELDY G. ALDERSON, and HOWARD ROBERTS Symposium on pre- and postoperative care Management of surgical jaundice and stomach cases diabetes in surgery, traumatic and postoperative pneumonia, cardiac and renal complications, postoperative psychosis; allergy in relation to abdominal surgery discussion and demonstration of cases

PERALTA HOSPITAL

- J. L. LORR—9 Cholecystectomy
 ERIC A. MAYNOR—9 Carcinoma of breast, radical removal
 F. M. LORR and JOHN W. SARRICK—9 Porto caval anastomosis
 CHARLES B. FOWLER—9 Orthopedic treatment of spondylolisthesis correction of upper extremity involvement in polyomyelitis
 H. J. TRIMBLE and J. LUXFORD—10 Electric desiccation in cutaneous malignancies
 JOHN W. SARRICK—9 Vaginal plastic
 T. FLOYD BELL—10 Pelvic tumor
 T. C. LAWSON—11 Hernia, fascial repair
 P. N. JACOBSON—11 Bladder surgery
 PAUL MITCHELL—9 to 1 Pathological demonstration and exhibit
 J. D. COATES—9 to 1 X-ray demonstration and exhibit

COWELL MEMORIAL HOSPITAL

- HENRIET EVANS, ROBERT LEOX, C. A. KOPF and associates—9 Exhibit and discussion of latest advances in endocrinology, inspection of laboratories and hospital with special reference to the systematic method of care of university students, discussion of laboratory technique with particular reference to anesthetics

ALAMEDA SANATORIUM

- J. OGDON—9 Hernioplasty under local anesthesia, appendectomy
 G. R. BURKE—9 Cholecystectomy
 CLARENCE HALL—10 Resection of stomach

FRIDAY EVENING

3:30 Evening Medical Sessions
 1. **Ear, Nose and Throat**—Vocal Hygiene and its importance.
 2. **Ear, Nose and Throat**—The value of the larynx.
 3. **Ear, Nose and Throat**—The value of the larynx.
 4. **Ear, Nose and Throat**—The value of the larynx.
 5. **Ear, Nose and Throat**—The value of the larynx.
 6. **Ear, Nose and Throat**—The value of the larynx.
 7. **Ear, Nose and Throat**—The value of the larynx.
 8. **Ear, Nose and Throat**—The value of the larynx.

EAST OAKLAND HOSPITAL

7:30 Dinner—Bar & Deck
 8:00 **Ear, Nose and Throat**—The value of the larynx.
 8:30 **Ear, Nose and Throat**—The value of the larynx.
 9:00 **Ear, Nose and Throat**—The value of the larynx.
 9:30 **Ear, Nose and Throat**—The value of the larynx.
 10:00 **Ear, Nose and Throat**—The value of the larynx.
 10:30 **Ear, Nose and Throat**—The value of the larynx.
 11:00 **Ear, Nose and Throat**—The value of the larynx.

SURGERY OF THE EYE, EAR, NOSE AND THROAT

CLINIC IN SAN FRANCISCO HOSPITALS—DAILY

UNIVERSITY OF CALIFORNIA HOSPITAL

Friday
 JOSEPH L. MCCOOL, FREDERICK C. CORDIS, JOSEPH W. CRAWFORD, C. ALLEN DICKIE and DAVID O. HARRINGTON—9. Ophthalmological operations.
 R. C. MARTIN and FREDERICK C. CORDIS—9. Tonsillectomy.
 WALLACE SMITH, LOUIS MORRISON and EDITH STOKER—9. Otolaryngological operations.

Dry Clinics—

FREDERICK C. CORDIS. Surgery of the internal canaliculi.
 J. W. CRAWFORD. Tuberculosis of the eye.
 C. ALLEN DICKIE. Surgery of the vertical muscles.
 DAVID HARRINGTON. Contact glasses, practical demonstration.
 R. C. MARTIN and STANLEY BURKE. Injuries and repair of the facial nerve.

Thursday

JOSEPH L. MCCOOL, FREDERICK C. CORDIS, JOSEPH W. CRAWFORD, C. ALLEN DICKIE and DAVID O. HARRINGTON—9. Ophthalmological operations.
 R. C. MARTIN and FREDERICK C. CORDIS—9. Tonsillectomy.
 WALLACE SMITH, LOUIS MORRISON and EDITH STOKER—9. Otolaryngological operations.

Dry Clinics—2

JOHN SAUNDERS. Regional anatomy of the mastoid and pathways of infection of the intracranium.
 HOWARD C. NAFZIGER. Brain abscess arising from middle ear and mastoid infections.
 WALLACE SMITH. Phlebitis and thrombosis following middle ear and mastoid infections.

Friday—2

FREDERICK C. CORDIS. Surgery of complicated cataracts.
 J. W. CRAWFORD. The eye in diabetes.
 C. ALLEN DICKIE. The value of orthoptic treatment.
 DAVID HARRINGTON. Tobacco amblyopia and its treatment.

ST MARY'S HOSPITAL

Thursday—2

FRANK COSLAN, STANLEY BURKE and FRANK HOWE. Treatment of posterior sinusitis. Blood dyscrasias in relation to the ear, nose and throat. Treatment of bilateral abductor paralysis.
 FRANK HOWE. Radical antrum.

SAN FRANCISCO HOSPITAL

Thursday

WARREN D. HUNTER. External indirect eye history, uses, advantages and advantages.
 C. ALLEN DICKIE and J. W. CRAWFORD. Safety procedures in contact operations: albinism, intra-ocular hemorrhage, 51 sutures, preoperative medication.
 WARREN D. HUNTER, C. ALLEN DICKIE and J. W. CRAWFORD. The use of methylene blue in the treatment of ocular diseases.
 ARTHUR RAWLINSON. Osteoma of the antrum: some curious foreign bodies in the lungs: cases of recovery from otitis meningitis: extensive osteomyelitis of the frontal bone.
 HARRINGTON B. CRAWFORD. Foreign bodies in the lungs, stenosis of the esophagus: cancer of the larynx.
 HARRINGTON B. CRAWFORD and J. M. WILSON. Extensive abscess of the meninges.
 RAY ASHLEY. Treatment of tuberculosis of the larynx.

HOSPITAL FOR CHILDREN

Thursday

GEORGE N. HOSKIN and AVERY M. HICKS. Technique for the determination of the hydrogen ion concentration of tears. The significance of pH of tears in ocular symptoms and treatment. Indications for and results of orthoptic training. Relation of vertical imbalance of extra-ocular muscles to gastric symptoms, posture, temperament and aptitude for school work and occupation. Congenital muscle palsies. Motion picture demonstration of O'Connor technique for heterophoria and heterotropia.

Days to be announced

GEORGE N. HOSKIN and AVERY M. HICKS—9. Extraction of congenital cataract, muscle operations, O'Connor clasp shortening for simple exotropia, simple esotropia, vertical deviations, muscle transplants for external rectus palsy, superior rectus for paralysis of the superior oblique (Jackson's technique), Alastair operation for congenital ptosis, Todd-Mowbray operation for occlusion of nasolacrimal duct (with Drs. Martin and Hosmer).

STANFORD UNIVERSITY SCHOOL OF MEDICINE

Wednesday

FRANK ROBIN. Congenital and hereditary eye defects.
 AVERY HICKS. Ocular torticollis.
 DONALD W. FISHER. Retinal detachment, methods and results.

MOUNT ZION HOSPITAL

Tuesday

HERBERT J. CONY, EDWARD LIPSETT and JOHN SCAFF—9
Tonsil operations, local and general anesthesia, dis-
section, Stader anastomosis

Wednesday—3

HERBERT J. CONY, EDWARD LIPSETT and JOHN SCAFF
Symposium on mastoidectomy
GEORGE S. LACHMAN. Treatment of corneal ulcers
CHARLES WEISS. Recently developed concepts in im-
munology and bacteriology of value to the ophthal-
mologist
FRANK H. ROBIN. Treatment of acute endocyclitis
G. Y. RUSE. Pathological demonstration of various eye
conditions

Thursday

Staff—9. Nasal operations. Submucous resection, electro-
coagulation of turbinates, sinus surgery

Days to be announced

FRANK H. ROBIN and GEORGE S. LACHMAN—9. Eye
operations. Cataract, strabismus, plastic on eyelids

SOUTHERN PACIFIC HOSPITAL

Thursday—2

WILBUR F. SWEET and JOHN C. WILLIAMS. Clinics and
demonstration of cases

CLINICS IN ALAMEDA COUNTY HOSPITALS—WEDNESDAY

PROVIDENCE HOSPITAL

A. J. HOWELL—9. Reconstruction of nose
RODOLPH O'CONNOR—9. Muscle shortening cataract Cur-
ran operation
GEORGE McCLEURE and NELSON KEELER—9. Ear, nose
and throat surgery
RANDOLPH SHARPSTEIN—9. Mottus' operation
ROY NELSON—9. Laryngoscopy and bronchoscopy
BRUCE STEPHENS, JR.—10. Cataract operation
FRANK BAXTER—10. Ear, nose and throat operations
MILTON H. SMITH—10. Ear, nose and throat operations
ALEXANDER GALLBRAITH—10. Ear, nose and throat op-
erations
W. A. MAGRATH—11. Eye operations
ALVIN P. WOLD—11. Eye surgery
F. C. KRACAW—11. Ear, nose and throat surgery

LETTERMAN GENERAL HOSPITAL

Tuesday

A. E. SCHLAUSER and HERBERT H. PRICE—9. Ton-
sillotomies, adenoidectomies, general anesthesia
HARVEY C. MAXWELL—9.30. Eye surgery, general
anesthesia. Strabismus correction by O'Connor
tendon crush and by Jamieson recession

Wednesday

A. E. SCHLAUSER—9. Tonsillotomies, local anesthesia,
nasal operations, local anesthesia

Thursday

HARVEY C. MAXWELL—9. Eye operations, local anesthe-
sia. Cataract extraction, pterygium transplant,
strabismus correction

Friday

A. E. SCHLAUSER, HERBERT H. PRICE and HARVEY C.
MAXWELL—9. Sinus surgery, local anesthesia, extra-
nasal radical frontal ethmoidectomy, radical
maxillary sinusotomy, bronchoscopy, criopharyngoscopy

ST LUKE'S HOSPITAL

Tuesday and Thursday

JOSEPH L. MCCOOL, C. ALLEN DICKIE, A. E. EDGERTON
and CHARLES BATES—9. Ophthalmological clinic

VETERANS ADMINISTRATION

Staff. Bronchoscopic examinations.

R. J. NUTTINO—12. Eye operations
P. T. LEITCHER—12. Ear, nose and throat surgery
FRANCIS SMOOK—12. Ear, nose and throat surgery
SYDNEY N. PARKINSO—12. Treatment of acute and
subacute paranasal sinus infections, lantern slides and
motion picture demonstration

Dry Clinic, 2—4.30 p.m.

Staff. Discussion of operative procedures, demonstration
of cases, lantern and motion picture demonstration

ALAMEDA SANATORIUM

B. M. STEPHENS—11. Cataract

CHILDREN'S HOSPITAL

M. E. LUND—11. Strabismus, operative treatment

SUBJECT INDEX TO VOLUME 60

ABDOMEN Phagedenic ulceration—its recognition and treatment, 304, Lymphangiomata of great omentum, 695

Abnormalities, uterine, Uterosalpingography by interrupted fractional injections, a modified and improved technique, 224 of kidney Resection, 984

Absorption, colonic, Studies on, and excretion in segments of colon of man, 667

Acid meal, Mechanism by which acidity of, is reduced in stomach, 966

American College of Surgeons—
 Address of welcome, Arthur W. Allen, 426
 Address of retiring President, Background of American surgeon, William D. Haggard, 427
 Approval of medical, surgical, and hospital equipment, instruments, and supplies, 610
 Cancer list of clinics approved to October 1, 1934, 592
 Symposium, curability of, 452-515
 Candidates, Presentation of class of 1934, 490
 Case history honor list and prize award, 451
 Clinical Congress of Surgeons, 1934, Transactions of in Boston, 257-634 Boston committee on arrangements, 617 Preliminary announcement San Francisco meeting, 1935 1152
